VOL. 84. NEW YORK, SATURDAY, JANUARY 2, 1904. NO. 1.

ORIGINAL ARTICLES.

THE MANAGEMENT OF TYPHOID FEVER EPIDEMICS.*

BY GEORGE A. SOPER, PH.D.,

OF NEW YORK;

EXPERT FOR THE NEW YORK STATE DEPARTMENT OF HEALTH IN THE SUPPRESSION OF THE ITHACA EPIDEMIC OF 1903.

IT has been said that for every epidemic some person should be hanged. This, like many other epigrams, contains a germ of sense, but upon analysis is found to contain a misconception. If it were customary to hold public officers strictly responsible for their acts and health boards were as familiar with the principles and precepts of hygiene as they are generally supposed to be, there is no doubt but that some person or persons would be punished as a result of most of our typhoid fever epidemics.

As it is, however, we act very irrationally about the whole matter. We first attribute to health boards a knowledge which they should not be expected to possess and then excuse them from responsibilities which the law has clearly placed upon them.

It is well to consider how health boards are constituted. The boards of health of cities are usually appointed by the mayor and confirmed by the council. In villages the health board is commonly appointed by the village trustees, although the trustees themselves or the president and council of the village may act as a board of health. The local boards of health of towns are constituted in various ways: the township board, consisting of the supervisor, two justices of the peace and the town clerk, may constitute the health authority, or the board may be elected by popular ballot. The boards usually meet at regular but infrequent intervals to transact such business as is brought before them. The proper transaction of this business requires the exercise of much tact and discrimination in order that the action of the board may be, on the one hand, just and sufficient, and on the other, not so severe as to entail unnecessary hardship and expense, but a knowledge of public hygiene is seldom thought to be needed. It is customary for one of the members of the board to be a physician, but beyond this no scientific nor technical knowledge is required of the members. As a rule, there is no salary attached to the office, service being rendered voluntarily and without remuneration of any kind. Because sooner or later public duties and private interests are very apt to conflict, membership, although regarded as an honor by those who do not possess it, often comes to be looked upon by the members themselves as a thankless and unpleasant service.

The most remarkable power is everywhere given to local boards of health for the performance of their duties. The law requires the use of all possible care to prevent the spread of infectious diseases, and where there is a divided opinion as to the sufficiency of means for the protection of public health, the law is that the more effective measure is to be adopted. If the circumstances require, the board of health has authority to enter upon private property and remove and destroy, and not simply disinfect, articles of clothing, furniture and bedding which may be thought to be tainted with infectious material. Persons may even be seized and restrained from their liberty, private houses converted into hospitals, and many other things done which under ordinary circumstances would be considered a gross outrage upon the rights of persons and property. The safety of the people is the supreme law.

For an improper exercise of the large powers which are vested in local boards of health, severe penalties are provided. Health officers do not possess any special immunity from responsibility for wrongful acts, as, for example, the performance of duties in a grossly negligent, reckless or otherwise improper manner.

Such skill in sanitary science as is possessed by the board is usually represented by an employe. It is the duty of every local board of health to appoint a competent physician, not a member of the board, to be health officer and to act as the sanitary adviser and executive officer of the board. Among the duties which devolve upon the health officer may be named the following: to carry into effect the sanitary laws; to cause every case of infectious disease to be reported immediately and to transmit the same to the state department of health without delay, to keep the local board of health informed concerning dangerous diseases; to discover and remove preventable causes of disease, and to this end to direct, under the authority of the local board, an efficient system of sanitary inspection; to receive and examine into the nature of complaints concerning nuisances and causes of danger to the public health; to supply the local board with a knowledge which will enable them to make public, information which may be useful in the prevention of disease and the removal of injurious conditions.

Theoretically, the health officer directs the active work of the board of health. He should be skilled in sanitary science, and should be able at all times to give and apply an accurate knowledge as to the causation of infectious diseases and the most approved methods of eliminating them.

*Read at the Third Annual Conference of Health Officers of New York State, Albany, October 9, 1903.

The health officer should have special training in bacteriology, chemistry, pathology and sociology in order that he may be properly prepared for his duties. Since his position is one of great responsibility, he should be well paid. As a matter of fact, his salary is usually less than one dollar a day, excepting in the larger cities. It is no wonder that the best men are not always available. Yet good men are needed to prevent epidemics.

It is a misfortune, and, I think, somewhat of a reflection upon our universities and medical schools, that a scientific training in hygiene and sanitation can scarcely be acquired in this country. It is not so in Europe. In England, health officers are required to have a diploma testifying to their fitness for the duties to which they are appointed. On the continent, nearly every university of importance has its professor and department of hygiene, while in some countries there are whole institutions devoted to the study of the cause and prevention of disease. In America, we have no training school for health officers, we have no degree of doctor of public health, and, although our state demands a knowledge of hygiene before granting a physician a license to practice, there is scarcely a school of learning where such a knowledge may be obtained. So long as our educators remain blind to the need of disseminating a knowledge of this important subject, we cannot expect high standards of efficiency in our boards of health. If the responsibility for typhoid epidemics were pressed home as in the adage, I believe that the universities would, in many cases, occupy prominent places at the hanging.

But the title of the present paper indicates that our attention is not to be directed so much to the prevention of epidemics as to their suppression. What shall be done when an epidemic has arrived? The first thing is to know when a real epidemic is on. Usually a rumor that an infectious disease is spreading rapidly through a community is the first intimation of trouble. This is followed by denials from interested persons whose business is threatened by the public fear. Sooner or later the facts insist upon acknowledgment and it is confessed that an epidemic has broken out.

The pendulum then swings the other way. Exaggerated tales of the progress of the disease gain circulation. If the epidemic is not soon checked, symptoms of panic become observable. The number of cases is probably not accurately known. To the physicians the disease may be of an unknown, or practically unknown, character. Many epidemics of typhoid fever are not recognized in the beginning to be typhoid, because of the large variety of puzzling symptoms which this disease frequently presents. We have heard typhoid fever pronounced to be each of a score of other diseases, the majority of them hitherto unknown and unrecognized in medical practice.

In the first hours of uncertainty and dread which follow the outbreak of an epidemic, it is imperative that the health board act with wisdom and celerity. Nothing can do more good than to take prompt steps to determine the presence and nature of the disease. In the diagnosis of typhoid fever, reliance should never be placed upon clinical symptoms alone, where these seem to be uncertain in character or masked by symptoms which baffle the judgment. To be on the side of safety, it is desirable that all cases of continued fever not positively diagnosed, when prevalent in a community, be regarded as suspicious of typhoid, and the patient and his surroundings regulated in a way that will prevent the disease spreading if the provisional diagnosis is correct. It is important that these provisional diagnoses be promptly made and reported to the local board of health. On or after the seventh day, if doubt still exists, samples of blood should be taken to be tested by the Widal reaction. Microscopic slides, with full directions for their use, may be obtained from the headquarters of the State department of health at Albany. These slides can be had in any reasonable number. They will be examined free of charge by the State department and the results communicated to the local board of health upon request.

As practitioners at large are not in the habit of making use of this aid to the diagnosis of typhoid fever, a word should be said as to the interpretation of the Widal results. If the report of a specimen of blood sent to Albany indicates that the Widal reaction was positive, it is safe to conclude that the patient whose blood has been examined has typhoid fever or has had that disease within a recent period. If the report of the Widal test is negative, it is not to be inferred that the patient has not typhoid fever; it may be that the sample was taken before the blood assumed its typhoidal character. In the event of a negative report, it is desirable that another specimen of blood be taken for analysis. It is not to be forgotten that the blood will probably not react before the seventh day of the disease, and that it may persist for several weeks and months after apparent recovery. When utilized to the fullest extent, the Widal test can be of the utmost value at the outbreak of an epidemic of a disease which is suspected to be typhoid.

When an epidemic of typhoid fever has settled upon a community and it has become apparent that some more than ordinary measures of public safety are required, it will be desirable that the local board be strengthened to meet the emergency. The question arises at once, how this can be best accomplished. It may be that the board contains within itself sufficient initiative and executive ability to bring about such changes as may be necessary. When local boards can rise to the emergency of a typhoid epidemic without unnecessary sacrifice of time or money, there will be no need of obtaining outside assistance. In most cases, however, it is believed that boards of health, when confronted by epidemic conditions,

will desire to obtain help if prompt and capable assistance can be secured.

Fortunately, provision exists for the assistance of stricken communities in this emergency. The state department of health, which by law exercises supervision and authority over local boards, may be called upon for aid and for such advice as may be needed in order to control the epidemic. A desirable way by which the state department of health may furnish assistance to a local board is through an expert representative. The representative should be provided with ample power and authority by the state department, and should act under broad instructions to secure the introduction of such measures as are most suitable and appropriate, the fact being clearly kept in mind that an epidemic of typhoid fever in any locality is liable to spread to other communities. The status of the representative of the state department of health should be clearly defined. His duties should be considered as simply advisory so long as effective work can be carried on by the local board, in this manner. The existing law of New York permits the commissioner of health of the state to dissolve incompetent local boards, and to appoint health authorities to carry on the functions of the local board when thirty days have elapsed without a new board being appointed. It would be desirable if the state department could authorize the representative to take charge without so long a delay. If, however, the circumstances warranted it, there is little doubt but that an immediate assumption of the desired sanitary control would be upheld by the courts.

Except in the most extreme cases, it is distinctly preferable for the state's expert to consider his duties to be those of an observer and an adviser, taking account of all matters connected with the epidemic, and giving counsel and instruction and initiating sanitary measures in an amicable manner. The advice is pretty certain to be accepted as the surest means of relief at hand. It was in this way that the local board of health at Ithaca was supported to meet the severest epidemic that this state has known for many years.

The second step in suppressing an epidemic of typhoid fever lies, in my view, in determining accurately how many cases of sickness there are, where they are distributed and when they occurred. There is no more indispensable feature connected with the control of an epidemic than the collection and intelligent analysis of the vital statistics. Although the laws specify that physicians shall report their cases of infectious disease to the local board of health, many are not, under ordinary circumstances, in the habit of notifying their cases accurately or promptly. In times of epidemic it is imperative that the health authorities make a special effort to have reports sent in in the most accurate and punctual manner. There are many ways in which to obtain these reports from the physicians: the law, which is binding upon the physicians, may be enforced, or the local board may seek to obtain the co-operation of the physicians in a friendly spirit. The latter method is preferable, especially in small communities, but in larger cities, where public health work is generally carried on with less regard for personal relations, the prosecution of a delinquent physician may be the most practicable way to obtain the needful data from the rest.

The facts collected from the physicians' reports should be carefully digested. Maps on as large a scale as feasible should be used to plot the location of fever cases, and tables should be made to embody the results in chronological order, as well as by sections of the city, village or town.

Special care should be taken to detect the existence of mild, unusual and atypical cases, since an epidemic is not so likely to spread from the severe cases as from the mild ones. It should be remembered that all kinds of transmissible diseases which ordinarily escape detection by the family physician are the most dangerous to the public. It is not the patient who is sick in bed and under the control of doctors and nurses, but the one who is well enough to travel in street cars, attend church services and other public meetings and, in short, be about his business and pleasure in nearly his usual manner, who is most likely to spread disease. The State's expert should be prepared to visit and consult with the local physicians in the diagnoses of all suspected cases, and should take such independent measures to detect mild or aberrant forms of the epidemic disease as are in his judgment proper.

At the earliest practicable moment, the original cause of the epidemic should be looked for in order that it may be removed if it still exists. In most cases in which an epidemic has progressed to alarming proportions, the first cause will have disappeared and many local foci of disease taken its place. In this event, the difficulty of investigating the sources of disease germs is greatly increased. It is important that each center be detected and surrounded with such protective measures as will effectively prevent the further spread of the fever.

It is well for the local board of health to remember that in investigating and inspecting premises on which dangerous or injurious conditions are thought to exist, the jurisdiction of the local board must not be overstepped. The jurisdiction of local boards of health extends no farther than the limits of the corporations from which their authority is derived. The health officer of a city or village has no legal right, unless by special authorization, to enter upon premises located in a neighboring city or village, or upon property in a township, even though the township limits include the city or village from which he may derive his authority. If, as frequently occurs, a health officer desires to make inspections in the territory which supplies his corporation with drinking water, milk or other commodity, authority for such inspections

must be obtained from the municipal corporation concerned or from the state department of health.

As food supplies play such an important part in the spread of typhoid fever, it may be well to repeat that local boards of health may control the purity of these articles by regulations covering the quality of these products as they are offered for sale in the city.

As disinfection on a large scale will generally be required in a typhoid epidemic, it is desirable that the board of health prepare and distribute disinfectants of standard quality, without charge, to all houses where sickness exists. Analysis of many samples of proprietary disinfectants on the market shows that they are often too much adulterated to be depended on. An indiscriminate use of disinfectants should be discouraged. It is preferable that a great deal of attention be given to their proper application. The choice of disinfectants to be employed and the manner of using them are matters upon which the representative of the state department of health should be qualified to advise. Milk of lime, made by adding four parts of water to freshly slaked lime, and bichloride of mercury, prepared one to one thousand, are among the most suitable disinfectants to be employed. The milk of lime should be used for the disinfection of excreta and urine, and the bichloride of mercury for all other purposes. In all cases, the destruction of infectious material should be carried on as near its source as possible. If the disinfectants mentioned are properly used, fumigation will not be necessary. Where fumigation is indispensable, formaldehyde, used by sprinkling the 40-per-cent. solution of formalin on a bed sheet in the proportion of one quart to a thousand cubic feet of air space, is recommended. In general, it will be disadvantageous, in my opinion, to employ those chemical agents which are properly termed deodorants or counterodorants. The use of germicides which have a distinct odor is regarded unfavorably by me.

A recent contribution to our knowledge of the infectivity of typhoid fever is that the urine may contain enormous numbers of typhoid bacilli, and that the infection of the bladder, which is the cause of this condition, may remain after the patient has been discharged by his attending physician. The percentage of cases in which the urine becomes infected is probably small, but the danger of spreading the disease through this channel makes it important that it be recognized. For the disinfection of the bladder, the use of several drugs has been recommended. Urotropin, given in 10-grain doses three times per day for a week, has been found to be effective.

Along with the more scientific work of checking the epidemic will probably come a popular movement for a municipal house-cleaning. To encourage this can do no harm; indeed, it is desirable that the public should be requested to cooperate and assist the health work in all possible ways. It is partly for this reason that the investigation of complaints made by citizens should form a conspicuous feature of the work of the sanitary organization. It is even advisable that inspectors be delegated to various districts to inquire into the sanitary conditions before they are complained of. Responsibility rests upon the board for prompt and just action in the suppression of nuisances. It is their duty to ascertain when conditions answer to the definition of nuisances, as defined by the sanitary ordinances. But care should be taken here, as in other directions, that the authority of the board be not exceeded.

Inasmuch as the expenses of local boards of health are met in the same way as the expenses of the other divisions of the local government, unless otherwise especially provided for by law, the local board, in time of epidemic, will need to obtain funds for its work. The board should obtain authority for the expenses necessary to accomplish the business in view. Failing in this, they may proceed independently, and the obligations incurred in the event of the performance of necessary work for the protection of the public health at a time of great emergency will bind the city, village or town which is concerned. The expense of disinfecting private premises and of furnishing medical attendance and nurses is properly chargeable to the patient himself, unless he is confined involuntarily or is a pauper, in which event the expense is chargeable to the county or town.

But to catalogue all the duties of the health authorities in the management of a typhoid fever epidemic is beyond the range of the present paper. Such a treatment of the subject might well constitute a treatise of formidable length. Typhoid fever in a small village, extended township or large city is a disease which, when in epidemic form, will require very different treatment in detail in order to accomplish its suppression. Local circumstances will always exercise a governing influence in determining just what steps should be taken. The foregoing remarks, therefore, are not intended to be in any sense a program, but are rather given for such suggestions as they may contain and in order to show that local boards of health, when overwhelmed by the difficulties which attend the outbreak of a typhoid fever epidemic, may appropriately apply for assistance to the State department of health.

I am aware that in expressing an opinion favorable to what may be considered a state management of epidemics I am recommending a course which appears to be different from that ordinarily followed in this commonwealth. But the difference is more seeming than real. It has been the custom on occasions of severe epidemic for the state department of health to send a representative to investigate the cause of trouble and to recommend measures for the elimination of the cause. The visit of the expert has usually been brief, two or three days ordinarily being considered sufficient for his investigation. The suggestion that I make is that the state send a representative to remain long enough at the seat

of epidemic to insure the adoption of measures which will bring it under control, whether this takes three days or three months. This suggestion, if adopted, would be in reality a development of the established custom of the state department of health and embodies no new features except an increase in the duties of the representative of the state and a corresponding increase in his authority in order to meet the requirements of the situation.

ANOMALIES AND DIFFICULTIES OF DIAGNOSIS IN TYPHOID FEVER.

BY HENRY L. ELSNER, M.D.,
OF SYRACUSE, N. Y.;
PROFESSOR OF MEDICINE, MEDICAL COLLEGE OF SYRACUSE UNIVERSITY.

ANOMALIES in the course of typhoid fever have ceased to surprise us. There are but few cases in which the critical eye fails to discover some anomaly. The difficulties of diagnosis, as a rule, end with the first seven or eight days of continuous symptoms. The type of the disease is likely to vary from year to year. There are some years of mild, others of severe and malignant types and still others in which are found all grades of severity. There is no acute infection which we meet in Central New York more *atypical* than that due to the *Bacillus typhosus*. Successive epidemics are likely to have some characteristic manifestations which cause them to differ from those of the previous years. The typical descriptions of Griesinger, Liebermeister, Lebert, Murchison and a score of other acute observers are not usually prototyped on this side of the Atlantic. Erratic, irregular and unique forms of the disease are interspersed with a majority of cases corresponding with the text-book résumé of our own splendid American authors.

In 1842 Bartlett in his work "On Typhoid and Typhus Fevers" despaired of our ability ever to be able to make an absolute diagnosis. He said, "Our diagnosis can never be founded here, as it is in many other instances, on a few positive physical signs. It must always be rational—not absolute. The evidence upon which our verdict is to be rendered is wholly circumstantial."

Murchison in his classic work says: "During the first week of the disease it may be impossible to make a positive diagnosis; but even then enteric fever may be suspected if there be pyrexia, with nocturnal exacerbations each night becoming more severe and especially if this be attended by diarrhea, enlarged spleen or epistaxis." Less than ten years ago if both the abdominal symptoms and the eruption were absent, the diagnosis of enteric fever was only reached by a "process of exclusion." It became necessary to compare symptoms with those of many other diseases with which typhoid was likely to be confounded and the majority of physicians clung to the Murchisonian rule that "a fever which persists beyond seven days and is unattended by cutaneous eruption, or by signs of local disease in the head, chest or elsewhere, is in all probability enteric fever, though there be no symptoms of intestinal lesions." This latter statement led to a decided advance in diagnosis and proved the clinical acumen and thoroughness of the author. Murchison adds "almost the only source of fallacy is latent tuberculosis." How eager would both Bartlett and Murchison have been to rewrite the chapter on the Diagnosis of Typhoid, if they had but lived to know of the conquests of bacteriology.

Yet the ever changing type of the disease; the irregularity of its invasion; the many foci from which the typho-toxin may overwhelm the victim, with the uncertainty of the life-history of the hardy disease-producing bacillus, the fact positively established, more important than the profession has yet appreciated, that typhoid infection need not spend its force in the intestinal tract, must of necessity obscure the clinical picture and were it not for the added knowledge gained by laboratory methods, we would still find ourselves unable to establish positive diagnoses in many of our cases until a period so late that these could as readily be made by the layman as by the scientist.

There is abundant proof that typhoid may recur in the same individual. The history of a previous typhoid ought never to preclude the consideration of a second attack. Our information may not always be accurate. On the other hand we must not forget that in some cases the blood of typhoids continues to show the characteristic reaction long after the acute disease. This may become decidedly misleading. In a Sister of Charity examined in St. Joseph's Hospital, in Syracuse, who was perfectly well, the characteristic reaction was present eighteen years after typhoid. The fact to be kept before our mental vision in considering this question is that the acquired immunity of typhoid is not of as long duration as is that of most other exanthemata and it is positive that this immunity does not protect during the entire life of the individual.

The study of the prodromal period of typhoid fever always interests us; it is replete with irregularities and has so many vagaries that with atypical symptoms during a few days following, we are puzzled and often much at sea. The invasion of the disease may cover a long period, during which there are vague symptoms none of which lead to more than a suspicion of approaching infectious disease. Indeed we have seen cases in which this prodromal period covered many weeks. Accurate thermometric measurements continued negative; the period was thoroughly afebrile; there were no localized abdominal symptoms; nothing but a feeling of ill health and malaise with occasional or continuous headache that foretold the approach of serious disease.

In another class of cases we are plunged at once from the prodromal period, which may not occupy more than two or three days, into the first week of the disease in which, without the characteristic rise of temperature, we have early

hyperpyrexia, delirium, with manifestations of profound involvement of the nervous system.

In still another class of cases the prodromal period is short; covers from three to four days and includes localized abdominal pains, often severe, slight diarrhea, temperature varies from 100° to 101½° F. and leads at once to a condition in which there are grave meningeal symptoms; the temperature rising from 104° to 106° F. per rectum, the pulse rarely above 100 and from this condition to a stage of hyperpyrexia, final increasing heart weakness, arterial tension below 100 mm., continual delirium, Widal reaction positive early, usually on the sixth day, increasing tympany, roseola on the seventh day; early incontinence of feces and of urine, which between the tenth and thirteenth days of the disease give way to constipation and retention of the urine. If the patient lives beyond the third week, the temperature is likely after that time to be almost normal; then during the next two weeks convalescence is satisfactory and uninterrupted. However, the majority of these cases do not rally from the profound nervous symptoms to which I have called your attention, but die without regaining consciousness, of cardiac asthenia between the fourteenth and seventeenth days of the disease.

Among the most malignant and anomalous cases are those—fortunately rare—of a foudroyant type. These are met in drunkards, those nervously reduced after prolonged worry and mental fatigue, in which there is practically no noticeable prodromal period but early high temperature and many symptoms of a rapidly fatal cerebrospinal meningitis. After the first forty-eight hours the arterial pressure falls below 100 mm.; the pulse is rapid; stupor is followed by coma in a few days, and the majority of these die before the tenth day. I have had occasion to autopsy a number of these cases and have found besides the usual typhoid lesions, marked cerebral congestions with in one abundant fluid in the ventricles of the brain. In all of these cases there were diagnostic features which aided materially. Among these we would emphasize the unusually tender and enlarged spleen, the great and early tympany, the copious diarrhea, with rectal and vesical incontinence, the hyperpyrexia, the absence of the Kernig symptom, the far-reaching evidence of profound sepsis and, finally, if the patient lived long enough, the positive Widal reaction.

I am reminded by several recent experiences connected with the Ithaca epidemic of cases in which the prodromal period is surprisingly short; the symptoms of the first week severe, the temperature reaching 104° F. During the first days of observation, the nervous symptoms are less profound than in the class of cases just described. The high temperature ends with the first week of continuous symptoms; the bowels become constipated and with a temperature during the two or three weeks following ranging from 101° to 103° F., most of the patients make a satisfactory recovery. With only a few days of high temperature, there is a fall of from one to two degrees in occasional cases and what appears to be a malignant typhoid becomes benign and leads to a favorable termination.

In connection with the study of the pulse it may be positively stated that in no other acute infection may there be such great disproportion between high fever and pulse rate. Uncomplicated cases show an average pulse not above 100. Typhoid may be considered a disease with low arterial pressure. We have recently made repeated observations of typhoids which have been admitted to St. Joseph's Hospital, Syracuse, and those seen in private practice, with the Riva Rocci instrument modified by Cook, and have satisfactorily demonstrated the truth of the statement that typhoid is a hypotensine disease.

Adult typhoid during the first week of continuous symptoms, shows the maximum blood pressure to be 130 to 140 mm. As the disease advances the pressure may fall to 100 mm. or even lower. In children the pressure is correspondingly lower. Thus a child aged twelve years, on the sixteenth day of the disease, during which the highest temperature had been 105.2° F. showed a blood pressure of 120 mm. At this time the temperature was 100.4° F., pulse 110 and respirations 25. A child of ten years, on the fifth day after admission, temperature 104.4° F., registered 134 mm. A young woman, aged sixteen years in the fifth week of the disease, during which the highest temperature had been 104.6° F., with normal temperature, respirations and pulse, showed blood pressure to be 135 mm. In children under six, the arterial pressure rarely registers above 100 mm. and usually lower.

Blood pressure study offers nothing of diagnostic value in typhoid; the only statement which we can positively make is that as the disease advances blood pressure falls, and at no time is it high without complications, usually abdominal.

In a correspondence which I have had with Dr. Briggs of the Johns Hopkins Hospital, who has made many interesting observations in connection with blood pressure, in typhoid and other diseases and to which I shall again refer in speaking of perforation, his observations and those made in the wards of his hospital agree fully with those which I have just mentioned.

During the first stage of the disease, the time when differential diagnosis is most needed the relative lowering and disproportion of the pulse and temperature is of greater value in diagnosis than is dicrotism. Dicrotism was present in the majority of our cases and is found oftener in typhoid than in other infections. A diagnosis ought never to be based upon the typhoid condition associated with dicrotism, for there are diseases in which the pulse continues dicrotic in which typhoid is simulated, dependent upon other than typhoid infection.

The association of a comparatively slow pulse, dicrotism, typhoid symptoms with enlarging spleen would naturally make us suspicious of ty-

phoid fever. In children with basilar meningitis, the pulse is rarely dicrotic, though slow and out of proportion to early high temperature, while the typhoid condition may be coexistent. In these cases the abdomen is retracted; there is constipation and usually with other characteristic symptoms the presence of the Kernig phenomenon. In the tuberculous form leucocytosis is absent, while those of pyemic origin, in which we are most likely to have typhoid simulated, there is a positive leucocytosis.

The large majority of our cases show but little variation in the leading symptoms, including characteristic behavior of the fever during the second and third weeks of continuous symptoms. Hemorrhages or perforation are always suspected when during these days we have a decided lowering of temperature.

Our temperature charts show a number of typhoids with decided and sudden drops to a normal and below without subsequent evidences of hemorrhage or perforation. In most of these cases we were unable from anything that transpired to explain this unexpected fall of the temperature.

In Central New York we are hearing less and less of gastric fever. Typhoids do occasionally begin with stomach and hepatic symptoms, then follows a so-called continuous fever with or without slight icterus, which soon shows the marks of a typhoid. In two of these cases we found typhoid cholecystitis which dragged a long and weary course. In none of these positive cases was the Widal agglutination delayed after the ninth day.

The close observer will note in the majority of cases during this prodromal period and the first days of the disease that the tongue is tremulous, this fibrillary twitching is characteristic and in doubtful cases with headache, slight enlargement of the spleen gurgling in the region of the ileocecal valve, has materially aided in strengthening a suspicion of typhoid before the Widal test became positive. I wish to accentuate the importance of this symptom, because I do not believe that sufficient attention has been given to it by the profession. This tremor is less marked in the typhoid condition associated with other infections.

In Central New York chills are the exception in uncomplicated typhoids. The diagnosis of typhoid must be surrendered if the patient has repeated chills. We have learned to exclude typhoid if with the chill there is leucocytosis and symptoms of infection. In cases where we have made the positive diagnosis of primary typhoid, secondary infection is usually present if chills persist. There are few cases in which repeated chilly sensations are absent; this symptom corresponds exactly with what the Germans speak of as "frösteln." We have no word in our language quite as descriptive of this symptom. Repeated chills with typhoid symptoms and even slight enlargement of the spleen during the early days of infection argue strongly against typhoid in favor of other infection. In connection with similar histories we have had very interesting experiences in some of which the diagnosis of typhoid had been made in which the leucocytic count and final physical examinations showed the presence either of endocarditis, malignant or benign, pus accumulation or some other form of grave infection. I shall later refer to the differential diagnosis of malignant endocarditis and typhoid. There are those who still believe that diarrhea and intestinal symptoms must be present before the diagnosis of typhoid is justified. During the prodromal period and the first week of the disease, we have often failed to find diarrhea.

In our study of 110 cases, diarrhea was present in 84 cases. Some of the anomalous cases have remained constipated throughout the entire course of the disease. The least valuable of all prodromal symptoms, formerly considered cardinal, is nosebleed. In the cases collected nosebleed was present in 49 cases. A small proportion of cases have had nosebleed late. This was occasionally an expression of a grave purpura.

The spleen gives valuable information, for in not a single case have we failed to detect its enlargement. I do not wish to convey the idea that we have been able to palpate this organ even in the majority of our cases. It seems to me that the American typhoid spleen is not as palpable as the German. Leube makes the statement that in 90 per cent. of his cases the enlargement is recognizable not only by percussion, but by palpation, if the examination is properly conducted. To this we cannot subscribe.

Our experience proves that young patients have larger spleens during typhoid than do adults and that the spleens of the latter if palpable at all are most likely to be so during the second week of the disease. It has been easier to palpate the spleen of children sick with the disease than young adults, for the proportionate enlargement of that organ is greater in infantile typhoid. I am aware of the fact that this has not been the experience of all observers, but a series of twenty cases of typhoid in children varying from ten months to ten years of age, closely observed, justify this statement.

In connection with the consideration of some of the anomalies of typhoid, we must mention the behaviors of the roseola. In but few of our cases have we failed to discover the eruption. In the 110 cases selected from hospital and private records which serve for the purpose of supplying the data for this paper, we failed to find the eruption in but 8 cases. In cases which have been observed, the appearance of the eruption was coincident with the seventh or eighth day of the disease. In some of our cases we have been forced to search diligently for the rose spots, so few being present and these at times in unusual locations. In a case observed before the days of the Widal test, in which there were many perplexing conditions, which masked the diag-

nosis, we finally found a single spot on the right wrist just before a copious intestinal hemorrhage.

In uncomplicated cases, we have never found the eruption hemorrhagic. Cases in which the diagnosis of typhoid fever had been made with ultimate hemorrhagic spots proved to be malignant endocarditis or some form of purpura either malignant or benign. Twice in our hospital experience we have had patients with enteric fever in whom we ultimately found *Roscola syphilitica,* coincident with the typhoid eruption; the typhoid infection having followed the syphilitic in from four to seven weeks, as near as could be estimated. Such experiences before the days of the agglutination test were puzzling.

In children, as well as in adults, scarlatiniform eruptions with typhoid have been noted, sometimes with throat symptoms, sometimes without. This may mask the diagnosis but with our present knowledge it would be possible even in the early stages of typhoid in similar cases and paratyphoids to reach definite conclusions from blood cultures, for the specific bacilli are present in the blood and can be easily demonstrated before the Widal agglutination. (Schottmüller, Rudiger.)

Hektoen emphasizes the value of this method of early diagnosis by the report of several cases; one in which typhoid was positively coincident with scarlet fever; two others in which there were suspicions of scarlet and typhoid in which the typhoid bacillus was readily demonstrated by culture experiment.

While the cultural method will readily confirm the presence of typhoid or paratyphoid, we will not quickly eliminate the diagnosis of associated scarlatina, a possible, though rare complication. The scarlatiniform eruption of typhoid will not ultimately desquamate and as De Costa demonstrated, it may persist or it may appear late, and return with relapses. It was present twice in twenty cases of children; in both it happened to be a late manifestation and followed the roseola.

In two per cent. of cases seen in private practice, I found the roseola eruption capped with a single vesicle at some time during its existence. Relapses have been, in the majority of cases, accompanied with recurring roseola.

In so-called ambulatory cases, the eruption has at times appeared after admission to the hospital (for most of these cases were hospital cases) or had been present before, or escaped detection. In none of our cases did we trace any relation between the number of rose spots and the severity of the disease.

There are but few cases of typhoid in which we fail to find some involvement of the sensorium, yet there are many which during the waking hours have the appearance of being absolutely clear mentally. A few anomalous but severe cases have remained comparatively clear during the febrile period to develop acute delirium later with mania and a long train of mental symptoms resembling the post-pyrexial mania of pneumonia. All of these have terminated favorably often after many anxious days.

In the series of cases under consideration there were two in which hemorrhages were severe and repeated before the end of the second week.

In December last I saw with Dr. Noyes, of New Berlin, a woman, aged forty-seven years, plethoric, who was thoroughly depleted by repeated severe hemorrhages before the eleventh day of continuous symptoms. The second case succumbed to an early profuse hemorrhage on the ninth day of continuous symptoms.

These cases may have been ambulatory for a longer or shorter period. Careful inquiry furnished no positive data. Cases in which there has been an unusually long period of indefinite symptoms, during which a feeling of ill health had not been considered of sufficient importance to claim the attention of the patient or physician, have occasionally been found with early hemorrhage and have shown great malignancy throughout the disease. The heart was weak from the beginning; the prognosis was unfavorably affected by early exsanguination. Two ambulatory cases came under observation moribund with perforation.

The diagnosis of abdominal conditions in typhoid is often exceedingly puzzling. No case of typhoid is so mild that perforation may not occur. There are no diagnostic means by which we can foretell the occurrence of perforation. There is no time after the beginning of ulceration until thorough cicatrization when in any case this may not occur without premonition. It is a positive fact that subjective and objective symptoms of perforation are not always associated with the rupture of an ulcer. All clinicians have been surprised by recovery of cases in which they had reason from the symptoms to suspect perforation. A localized peritonitis over a typhoid ulcer may exist before its perforation and may thus protect the free peritoneal cavity. A typhoid ulcer about to rupture may be covered by plastic material; the intestine may become adherent to a neighboring coil *without ultimate rupture* with symptoms of localized peritonitis only.

Griesinger many years ago, in his memorable article on typhoid fever made the following statement: "Evidently, in consequence of deep ulceration from within and sloughing, there frequently results, even before perforation, a localized inflammatory process, with adhesions of the inflamed patch to the neighboring intestinal coils. In such cases there is not at once perforation into the free peritoneal cavity. There is, however, a formation of circumscribed exudation, with or without suppuration, which may ultimately lead to a general peritonitis, though it may possibly remain circumscribed and gradually end in recovery. If there has been no adhesive process before the perforation, gas and intestinal contents escape into the free peritoneal cavity and general peritonitis immediately results."

In a paper read before this body "On the Perforation of Typhoid Ulcer with Adhesive and Protective Peritonitis," in 1892, the author re-

ported a case of perforation of a typhoid ulcer with adhesive and protective peritonitis in which the patient ultimately died of other intercurrent causes and in which a localized peritonitis with tumor simulated perforative appendicitis very closely. Post mortem showed adhesive localized peritonitis which served to protect the general peritoneum.

It will be difficult at times in some of these anomalous cases with perforation or with localized peritonitis early and tumor in the region of the appendix, to make a positive differential diagnosis. Prof. Fitz has collected 167 cases of perforated bowel in typhoid in which he found the appendix perforated in but five cases or a little less than three per cent. Murchison found this perforation only once in 39 cases. Morin found perforation of the appendix in 18.75 per cent. of typhoid perforations and Herschel in 14.3 per cent. It is difficult to reconcile the differences of the various writers. It would be easy to establish the existence of ulceration and perforation of the appendix with typhoid fever if it were frequent. The diagnosis becomes important in ambulatory cases in which patients come to the hospital with symptoms of perforation with tumor in the region of the appendix. In these cases a leucocytic count and the Widal test with a consideration of all that the case offers will not long leave us in doubt. An error of diagnosis would not prejudice the patient's chances for the aid of surgery would be invoked for either condition.

A number of years ago the elder Flint held that effacement of liver dulness was one of the most characteristic signs of perforation. It would be rather dangerous to accept this statement and base a positive diagnosis upon it. There are many cases of typhoid in which the abdomen is abnormally distended, with effacement of liver dulness in which there may or may not be evidences of localized peritonitis and yet perforation has not taken place. An unusually distended transverse colon may so modify the area of liver dulness in these cases as to cause tympany anteriorly over the area of normal liver dulness. On the other hand with perforation, adhesive inflammation, incapsulation, bands or from other causes, air may be held within a circumscribed area in the lower half of the abdomen without effacement of liver dulness. Careful examination of the abdomen will reveal the presence of the first source of error by placing the patient upon the left side and percussing in the axillary line on the right side over the liver from the eighth rib downward; the presence of free air in the peritoneal cavity showing itself by a disappearance of dulness in that line, while there would be a persistence of dulness if the anterior tympany had been caused by the distended transverse colon.

Mechanical irritation of the peritoneum during surgical operations causes a decided rise of systolic blood pressure; this can be established by means of the sphygmomanometer and is positive. Peritoneal inflammation either local or general from whatever cause, has the same effect on blood pressure during the early hours of its existence; a fact which proves of diagnostic value as the following shows:

Crile* reports: "In five cases diagnosed perforation, in which blood pressure determinations were made, four were verified either by operation or autopsy. The case not operated on was a typical one. The pressure rose from 116 mm. to 190 mm. during four hours. The second case, a lad of twelve years, was admitted to the Lakeside Hospital with general peritonitis. Blood pressure was 105; Widal reaction was positive. Immediate operation was performed and perforation found. Later the abdominal symptoms of peritonitis disappeared. The blood pressure fell to 80 mm. On the eighth day infection passed through the thinned wall of another ulcer, causing peritonitis; blood pressure then rose promptly from 84 mm. to 110 mm. In the third case, a patient in the ward at Lakeside, developed a slowly forming perforation, blood pressure rose from 116 mm. to 165 within two hours. The pulse in the meantime had but slightly increased. At operation a small perforation and diffuse peritonitis were found. The fourth case, that of a physician who entered Lakeside with general peritonitis, blood pressure was 165; no operation. Autopsy revealed perforation and diffuse peritonitis. The fifth case was one of typical perforation, blood pressure 208 mm. At operation perforation and diffuse peritonitis were found. The blood pressure in the perforation cases assumed the high level attending peritonitis from other causes."

Dr. Briggs,† of Johns Hopkins Hospital reported a similar experience in which the systolic blood pressure rose from 106 mm. to 144 mm., coincident with perforation proven by operation.

The results are suggestive and emphasize the importance of frequent daily observations of blood pressure in the course of typhoid fever that changes may be promptly noted and when considered with subjective symptoms and physical signs lead to an early recognition of localized peritoneal inflammation and intestinal perforation.

With repeated chills after typhoid and the persistence of fever, the involvement of the mesenteric glands in a process of suppuration must be kept in mind. Infections leading to prolonged typhoid sepsis may be continued by general pathologic changes or localized disease in one of many organs of the body with or without local symptoms. This is particularly true of typhoid infection of the bile passages and gall-bladder. Persistent jaundice in the course of typhoid must lead to repeated physical examination of the bile passages and gall-bladder for the purpose of detecting possible typhoid cholangitis or cholecys-

titis. The differential diagnosis of nephrotyphoid and typhoid in which the albuminuria is due to a pre-existing chronic nephritis, without positive knowledge of previous disease, may be strengthened by the study of blood pressure. This fact we have recently demonstrated in a number of cases. There are at the present writing two cases of albuminuria associated with typhoid at St. Joseph's Hospital the one a pure nephrotyphoid, the other a typhoid with pre-existing chronic diffuse parenchymatous nephritis. The blood pressure in the latter has been uniformly high; at the height of the disease it registered 168 mm. The blood pressure chart shows no record below 140 mm., while in the nephrotyphoid the highest arterial pressure registered 130 and as the disease advanced, repeated tests showed the fall of the ordinary uncomplicated case.

Among the most difficult cases to differentiate are those of malignant endocarditis of the typhoid type which bear close resemblances to typhoid and paratyphoid infections. These are rarely diagnosticated during the early days of the disease, but are considered typhoid fever. This is also true of cases of malignant endocarditis in which there are no positive early physical signs of the disease. In the type of malignant endocarditis known as the chronic type, which may appear with acute typhoid symptoms, we have at least the previous history of endocarditis to guide us and are largely influenced by the mutability of physical signs and the associated secondary manifestations. The most difficult cases are those in which the primary infection is hidden in which typhoid symptoms develop and in which the endocardium may be plastered with vegetations before the valves are sufficiently changed to cause audible physical signs of endocardial involvement.

This statement is equally true of those cases of gonorrheal endocarditis, some of which have ended fatally in a few days or weeks with typhoid symptoms. There are cases of malignant endocarditis in which the typhoid condition has followed pyemic symptoms, bearing the closest subjective resemblances to typhoid fever. Profuse hemorrhage is unusual in malignant endocarditis. In connection with this subject one fact must always influence our diagnosis; it is the positive rarity of endocarditis as a complication of typhoid fever. The truth of this fact will be received without hesitation if the pathologic records of large hospitals and private practice are studied.

Considered collectively typhoid shows a surprisingly small number of permanent heart lesions during the acute febrile period or following. With evidences of endocarditis and the typhoid condition, we shall always feel justified in assuming that the disease is not typhoid fever. It is this knowledge which must serve as a fundamental principle in the differential diagnosis of these conditions.

In a paper "On the Resemblances of Endocarditis to Typhoid and Paratyphoid Infections," I made the following statements; which I repeat at this time, because clinical experience has repeatedly emphasized their truth. "In the presence of murmurs with infection, the presence of petechiæ, disturbed circulation, infarcts and leucocytosis, negative Widal, we may strongly suspect malignant endocarditis. To make the diagnosis positive ante mortem, we must have the presence of physical signs referable to the heart and these we have in the majority of our cases before death. The presence of embolic infarct is a valuable diagnostic fact; it means much. It matters not how few evidences of embolic infarct we have, if we have any, and these are associated with limited cardiac changes and the presence of few general symptoms, we are compelled to suspect the possibility of malignant endocarditis."

Transitory or even lasting paralyses in the history of acute general infections are exceptional, except in those processes associated with embolic detachment and consecutive tissue change. These are frequent in typhoid types of malignant endocarditis.

Chills are frequently present during the early days of malignant endocarditis. The pyemic type of this disease may suddenly assume typhoid characteristics. The involvement of the right heart out of all proportion to left sided disease, with typhoid symptoms always argues against typhoid and in favor of malignant endocarditis. Cases of chronic endocarditis previously recognized in which true typhoid infection is present show none of the changes so frequent in malignant endocarditis. Typhoid fever uncomplicated during the first week of its existence, is not associated with leucocytisis. Leucocytosis at this time with polymorphonuclear increase is always strong evidence of infection other than typhoid. The specific germ if found in blood culture experiments will often help us materially in recognizing not only the port of entry but will clinch the diagnosis as well. Repeated negative blood cultures make the presence of malignant endocarditis unlikely, while if the disease be typhoid or paratyphoid the cultural methods will give early positive results. The difference in the differential counts of the leucocytes in typhoid recently reported to the profession by Thayer and Higley respectively prove conclusively that we are not yet agreed on the morphological relations of these cells to each other in this disease. All observers are agreed however that in typhoid, the white blood count is not increased and that a positive leucocytosis associated with typhoid symptoms, argues strongly against typhoid fever. The spleen of typhoid is usually larger than is that of malignant endocarditis. It is clear then from the consideration of the differential diagnosis of the malignant types of endocarditis and typhoid that with repeated painstaking physical examinations, daily leucocytic blood counts, blood cultures and repeated Widal tests, the diagnosis

need not remain doubtful long, but can be accurately and positively made.

The diagnosis of infantile typhoid is rarely made positive during the early days of the disease. It is equally true that a large number of infantile typhoids remain unrecognized because of the failure of the physician to appreciate the fact that infants and children are oftener infected than was formerly supposed. Occasionally we find children attacked when the older members of the family have escaped.

The roseola may or may not be abundant. In twenty cases ranging from ten months to ten years it was positively present in 65 per cent. Occasional cases have presented large crops. A single rose spot was found in two of my cases. One case presented a scarlet eruption without final desquamation. Continued fever in a child without localized disease with enlarged spleen, must lead to the suspicion of typhoid.

We have met the remittent type of the disease to which Murchison called attention. Quinine formerly aided us in diagnosticating these cases; now the Widal test gives positive information before the eighth day, rarely later.

Experience justifies the statement of Murchison that idiopathic remittent fever in children is almost invariably enteric. Cases of infantile typhoid have rarely continued febrile beyond the third week. Intestinal symptoms have been frequent; nervous symptoms were present in the majority of cases.

The short course in children is undoubtedly due to the absence of extensive deposits in the submucous intestinal tissue and sloughing of the diseased patches in large masses as in adults. Fewer glands are involved. Generally speaking it may be assumed that the positive signs and blood conditions with characteristic reactions are as dependable as in adult life. Miliary tuberculosis, central pneumonia, sepsis, pyemia, meningitis, entercolitis, influenza and malarial poisoning can, as a rule, be differentiated in early as well as in adult life by careful attention to detail and the employment of such methods as are today used by every anxious and scientific observer; though occasionally owing to late reaction and other anomalous conditions there may be days of uncertainty.

Time does not allow the differentiation of each of the conditions suggested. I may be pardoned, however, for calling your attention to a few facts: Hurried respiration, with typhoid symptoms, and associated leucocytosis in children or adults, are opposed to the diagnosis of typhoid. Sudden, repeated, unexplained vomiting in children with a low continuous fever, a slow pulse, changed disposition, constipation with or without cerebral macule and absence of enlarged spleen, argue against typhoid, in favor of approaching tubercular meningitis.

A continued fever in a child or adult following an injury with or without chills and the typhoid condition must lead to thorough blood examination. If leucocytosis is present, whether the spleen is enlarged or not, typhoid fever may be excluded. Sepsis, pyemia or endocardial infection must be considered.

The Ehrlich diazo reaction is not of positive diagnostic value, though it is found in most typhoids. Its presence in diseases other than typhoids makes it of uncertain value. It arouses suspicion; can never confirm diagnosis, as do blood cultural methods and the Widal test.

It has been manifestly impossible, in the limited time at my disposal, to consider in detail more than a few of the anomalies and difficulties of diagnosis which, in practice, we are constantly facing. I have been content to limit myself to such conditions as have been found of greatest interest to the busy worker in the broad field of general medicine. If I have succeeded in demonstrating the diagnostic value of the association of modern scientific methods with accurate bedside observations, *without the surrender of a single clinical fact made positive by such study*, I shall feel that the object for which I have labored in this symposium has been accomplished.

MANAGEMENT AND TREATMENT OF TYPHOID FEVER.*

BY EGBERT LE FEVRE, M.D.,
OF NEW YORK;
ASSOCIATE PROFESSOR OF THERAPEUTICS AND PROFESSOR OF CLINICAL MEDICINE, UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE.

THE consideration of the treatment of typhoid fever at the present time must seem to many of you like thrashing over old straw, so hackneyed is the theme. It is often of value to review our therapeutic beliefs and measures, and to see if they have kept pace with the advances in bacteriology and pathology; or whether, on the other hand, the old conception of the disease still dominates our treatment, and whether or not we have fallen into a routine method of treating our patients as soon as the diagnosis of typhoid fever is made.

I fear that in our treatment we too frequently lose sight of the fact that typhoid fever is a general infection with varying degrees of toxemia, and that the bowel lesion is not the prime factor, but only one of the pathological incidents of the disease, and may be entirely wanting.

Nursing.—It is necessary to insist on good nursing, for everyone concedes that more lives are saved by nursing than by any other part of the treatment, but we cannot always insist on the patient being taken to a hospital if the needed attention cannot be given at home.

For nursing to be efficient it must be skilled nursing and not that which can be given by the different members of the patient's family. Fortunately nearly every community is supplied with well-trained nurses. If the patient must be nursed at home by his family and friends, then it is our duty to see that it is not done by them indiscriminately according to the exigencies of

* Read at Symposium on Typhoid Fever October 14, 1903, at a meeting of the New York Medical Society.

the household work, but certain members should be assigned to this duty and the physician should insist that they be in attendance at regular hours and be relieved from all other household cares. If possible the room should have a sunny exposure and means for good ventilation. The bed should be protected against soiling, and if possible, the room should contain two beds, so that the mattress and coverings of one bed may be thoroughly aired and sunned each day. The covering of the patient should be light, and in private practice the physician should see that solicitous friends do not weigh the patient down with bed-clothes and so prevent as far as possible all heat dissipation.

There should be perfect cleanliness of the patient's person, especially the buttocks and genitals, for even in hospital wards one too frequently finds these parts imperfectly cleansed after defecation and urination, and it is necessary for the physician to inspect them personally to see that his orders are carried out.

While the dangerous nature of the stools is appreciated by all, the fact, that at certain stages of the disease the urine contains immense numbers of typhoid bacilli, is overlooked. Petruschky estimated the number of bacilli per cubic centimeter in three cases and found them 20,000, 5,000,000 and 172,000,000 respectively. There is greater danger of contamination of the food, etc. from the urine than from the feces.

Diet.—In the management of typhoid fever the diet presents the greatest problems, for, not only must we consider the food from the standpoint of its chemical composition, but also its influence on the local lesion and its remote effect, as well as whether it is suited to the individual case. Probably no part of the treatment of typhoid fever is considered by the majority of the profession so definitely settled as the question of food. In no other infectious disease is the diet so restricted and routine. In no other ulcerated condition of the bowels is there so great a fear as to the effect of the use of a variety of food and of adequate alimentation. This fear is largely theoretical and based upon the old conception of the nature of typhoid fever.

In no other disease do we disregard to the same extent dietetic principles and fail to adapt our food to the individual needs of the case, remaining blind to symptoms which are referable to too restricted diet, but which are usually ascribed to intestinal lesions or to giving other food than milk. The diet should be (*a*) liquid, (*b*) easily digested, (*c*) easily absorbed, (*d*) the unabsorbed portions or residue by the time it reaches the ileum should not contain any solid particles, (*e*) the food itself or its residue should not too readily undergo putrefactive or fermentative changes, (*f*) it should contain all the ingredients necessary in normal relative proportions, (*g*) it should be relished by the patient, or, at least, should not cause disgust or nausea.

Milk is considered the orthodox food, and one is considered a dietetic heretic, if, in typhoid fever, its all-sufficient power is questioned and any other suggested; nevertheless, it is necessary to consider whether milk meets, as we have been led to believe, all the requirements of an ideal and sufficient food in typhoid fever.

Although milk is taken as a liquid, as soon as it enters the stomach it is coagulated into masses of varying size and degrees of hardness. While these masses of curdled milk are readily broken up and digested in the normal stomach and small intestine, in typhoid fever, perfect disintegration of the masses occurs with difficulty, and as the feedings occur at short intervals there is not sufficient time for digestion to be completed; as a result the curds frequently reach the ileum in an irritating and dangerous condition. If anyone doubts this tendency he has only to inspect the stools of typhoid fever patients to see the frequency with which they contain hard masses. Physicians too rarely make it a routine practice to critically examine the stools to note the condition of digestion—frequently they do not even inquire concerning their nature, but are interested only in their number.

I can confirm the statement that under an exclusive milk diet of 60 to 70 ounces a day, the stools are larger and contain more undigested food than with a mixed liquid or semi-liquid diet containing the same amount of proteids, carbohydrates and fats. The modification of milk by dilution or by the addition of lime water lessens to a slight degree the above tendency. When milk is not perfectly digested it furnishes a good culture medium for the intestinal flora, with autointoxication from the products of putrefaction and fermentation.

In the treatment of other acute infectious diseases of the intestinal canal, experience has shown the necessity of withdrawing milk from the dietary for a longer or shorter time. In these diseases we recognize the fact that putrefactive and fermentative changes in the intestinal contents can increase the inflammatory condition of the bowels and cause systemic intoxication. In typhoid fever these secondary effects may be induced by the intestinal contents late in the disease, entirely independent of the histological changes caused by the typhoid bacillus.

Many patients cannot take milk at all as it causes epigastric heaviness, pain, pyrosis, eructation and abdominal distention (tympanites). In giving milk in other diseases the rule is to begin with a small amount and gradually increase until the patient's digestive apparatus becomes accustomed to it, so as to avoid the unpleasant symptoms mentioned. In typhoid fever, however, as soon as the diagnosis is made we immediately begin to feed entirely on milk, giving frequently during the first days as much as two or three quarts. It would be very instructive if every physician would experiment on himself and note the sensations following the taking of two or three pints of milk a day. The uncomfortable distention of the abdomen with its annoying and noisy accompaniment would soon impress upon

him the need of caution in giving to a patient with acute intestinal catarrh this amount of milk.

The most important requisite for a food in any exhausting disease, is that it should contain all the ingredients necessary for nutrition in normal relative proportions. In health a man needs 3,000 calories, which are supplied by 100 to 125 grams of proteids, 400 to 500 grams of carbohydrates, and 50 to 100 grams of fat; or, if estimated in relation to nitrogen and carbon, he should have proteids enough to give 17.5 grams of nitrogen and non-proteids sufficient to give 270 grams of carbon.

The ideal foodstuff should have the different ingredients in the following proportion: proteids 12, carbohydrates 50 and fats 5. In milk these proportions are: proteids 12, carbohydrates 20 and fat 18. The deficiency in carbohydrates and the relatively higher percentage of fat, causes milk to be inadequate for an adult when used alone.

On the basis that the diet should contain 110 grams of proteid to give 17.5 grams of nitrogen and non-proteids to give 270 grams of carbon, Munk has estimated that on an exclusive milk diet, six pints would be necessary to give the necessary proteids, and eight pints for the non-proteids, which is a greater quantity than most patients can take and digest.

If the milk given does not yield the necessary amount of nutritive material, then there will result a condition of partial starvation, in which the proteids of the body will be called on to make up the deficiency, and from this cause alone there will be a progressive loss of weight and strength.

In typhoid fever there is great proteid loss which cannot be equalized by the proteids of the diet although it may contain the 110 to 125 grams of proteid. It is important to shield the proteids of the body from the destructive process as far as possible, by the administration of carbohydrates and other energy-sustaining foods.

Recovery in all infectious diseases depends upon the resisting power of the patient. In typhoid fever, where we have no specific against the bacillus or its toxins, our only hope is to sustain the strength and nutrition and to preserve to the highest this power of resistance. If, during a long period of typhoid fever, the patient is kept on an insufficient diet, the resistance will be lowered and the bacilli will regain the ascendency so that we will have a recrudescence of the fever or a true relapse. I am thoroughly convinced that many of our cases of prolonged fever attended with marked physical exhaustion and cardiac weakness, are not due to the typhoid bacillus or its toxins alone, but to the lack, not of food, but of nourishment; for, under the exclusive milk diet of 60 to 70 ounces a day, our patients are overfed but undernourished.

The trouble is that as soon as we make the diagnosis of typhoid fever, we take counsel of our fears in relation to the diet and do not use the same therapeutic judgment as in other diseases. Since giving a diet richer in carbohydrates and albuminoids I have not seen the same weakness and emaciation following the first two weeks.

Professor Delafield has lately called attention to a condition named by him "post-typhoid sepsis" and characterized by fever and profound weakness which rapidly improves when the patient is given solid food and is also taken out of bed. A number of years ago my attention was called to these cases both in hospital and private practice, and while I have never been able to convince myself that the majority of them were due to a distinct sepsis, I have always considered that the symptoms were dependent upon a condition of partial starvation complicating an infectious disease of long duration.

Professor Wright and Lieutenant Knapp of the Army Medical School of Great Britain, have investigated the cause of thrombosis in typhoid fever, and have found that the coagulability of the blood is decreased during the early days of fever, but that it is increased beyond the normal during the later weeks and during convalescence. The increased coagulability they found was dependent upon an increase in the amount of lime salts in the blood, which increase is due to the calcium oxide derived from the cow's milk which contains one part in 600 as compared with one part in 800 in lime water. If this contention is true, then not only is an exclusive milk diet predisposing to thrombosis, but the liability thereto is still further increased by the use of lime water which is so commonly employed to dilute it. To overcome this tendency to an excess of calcium oxide in the blood, they suggest partial decalcification of cow's milk by adding citrate of soda (grains 20 to 40 to the pint).

The profession have, I think, adopted the rigid and restricted milk diet mainly because of its use in large hospitals. In institutions where great numbers of cases are treated, a routine diet is necessarily the best, as it guards against the giving of injurious articles by friends, and it is impossible to consider the individual likes and dislikes to the same extent as in private practice. In fact, the majority of our hospital patients do not have such fastidious tastes and such fickle digestive tracts as those in the higher walks of life; their usual diet is of necessity monotonous and variety in sickness is not so essential. But, even in these cases, I am positive that relapses would be less frequent, convalescence not so protracted, and the death-rate from complications lower, if a more varied diet were used. I do not mean that I would exclude milk from the dietary, nor do I advocate indiscriminate feeding. Indeed, one who uses a variety of food must exercise greater tact and judgment than when milk only is given, and unless he is willing and able to adapt the diet to the individual case and is also competent to give definite instructions for the making of the different preparations ordered, it will be safer for him to adhere to the exclusive milk diet.

I have one rigid rule in the giving of different foods, viz., that nothing is to be given to the pa-

tient during the early weeks of the fever that has not been or that cannot be passed through a fine wire sieve. In order to give variety to the diet and to supply the necessary nutritive elements the following preparations may be selected:

Drinks.—Pure water or mineral water from which the excess of CO_2 has been allowed to escape may be given ad libitum. It is not merely necessary that water be ordered, but care must be taken that it be given in large quantities. If possible the same type of water should be given as the patient is accustomed to, as frequently another type (hard, soft, etc.) will give the patient gastric distress and may cause diarrhea. To make the water more palatable it may be acidulated with dilute hydrochloric acid and occasionally with lemon or orange juice, or, a small amount of red or white wine may be added, although it is generally better to give it pure.

Milk.—Under the mixed diet it is rarely necessary or wise to give more than two pints a day, and the feedings should be separated by the giving of other foods. It is well to flavor the milk with coffee, cocoa or tea, or, if the patient has been accustomed to take either coffee or cocoa in the morning and desires it, it may be allowed. Putting milk in a shaker with a lump of ice and thoroughly aerating it makes it more palatable and digestible. Other milk products as koumiss, junket, etc., may be used to give variety. In order to increase the carbohydrate contents of the milk there may be added some stale bread which has been grated and passed through a fine sieve, or, instead of the bread, some of the farinaceous baby-foods.

Carbohydrates.—These may be given as mucilaginous soups made of oatmeal, rice, wheat, barley, tapioca or sago, either alone or mixed with bouillon. It has been claimed that the carbohydrates in the above forms tend to undergo fermentative changes in the intestines and that their digestion is especially difficult in typhoid fever. This objection is largely theoretical. Experience has proven that they are easily digested. When combined with milk and eggs, in the form of puddings, etc., they do cause flatulency.

Proteids.—Concentrated proteid nourishment must be given with great caution during the febrile stage. Usually that contained in the milk is sufficient. Egg when combined with milk is difficult of digestion. Egg-water, made according to the formula of Professor Osler (thoroughly shaken with ice, strained and flavored with lemon, sherry or brandy) may be given as a refreshing drink between the heartier articles of food. Yolk of egg stirred in bouillon or cereal soup should be given only after the fever has subsided and digestion has improved. The use of somatose, tropon, plasmon, etc., has been advocated, but personally I have had very little experience with their use in typhoid fever, as I prefer to give those preparations with which I am most familiar.

Gelatine.—The value of gelatine as an article of diet in typhoid fever has been underestimated. While it cannot replace the proteids it has the power to lessen nitrogenous waste and is more efficacious than either fats or carbohydrates in protecting the proteids of the body and so conserving both nutrition and energy. It is valuable for adding relish to the food with which it is combined and can be given as calf's foot jelly or by adding it to soup or broths. An especially grateful preparation is a cold jellied bouillon made by obtaining the gelatine from the bones and connective tissue of soup stock. I generally suggest that this be prepared from a shin bone of beef and a knuckle of veal. In addition to its value as a food product, gelatine is indicated in the later stages of the disease when there is danger or tendency to hemorrhage. Care must be taken, however, not to give it in excessive amounts as it has a tendency to increase the diarrhea and sometimes causes tympanites. When hemorrhage occurs and there is a rapid discharge of blood from the bowels, I have found that the use of a half ounce or an ounce of commercial gelatine dissolved in a pint of water and given in two to four ounce doses at frequent intervals, will very often have a marked effect in controlling the hemorrhage. I consider it more reliable than the use of ergot or the ordinary astringent preparations. In order to obtain the full nutritive value of the diet it is frequently necessary to supply the deficiency in the salivary, gastric and pancreatic secretions as well as the hydrochloric acid.

Cathartics.—The thorough removal of the undigested and unabsorbed residue from the intestinal canal is as important as the administration of food. In all other inflammatory and ulcerative diseases of the intestine this fact is well recognized and acted upon, but in typhoid fever the intestinal lesions presumed to be present have been considered a contraindication to the use of cathartics, and when certain cathartics have been given they have been used more as specific antiseptics or disinfectants than for the simple cathartic effect.

When there is ulceration of the ileum there is a tendency to retention of fecal matter above the site of the ulcers and there may be marked accumulation although the patient is having frequent small diarrheal discharges. This tendency to acumulation is increased by paralysis of the gut, with or without peritoneal involvement. I cannot insist too strongly upon the importance of thorough emptying of the intestines, as it is a frequent experience in both hospital and consultation practice to see patients with persistent diarrhea, tympanites, high temperature and profound toxemia, due to large fecal accumulations of partially digested food. These accumulations may occur although the routine daily enema has been given, but more frequently it has been omitted on account of the diarrhea.

The requisites of a cathartic for typhoid fever are (*a*) that it should thoroughly cleanse the small and large intestine, (*b*) that it should not cause markedly increased peristalsis or griping

(*c*) that it should not derange the digestion, and (*d*) that it should not produce any effect beyond that of a simple cathartic action. Only two classes of cathartics meet these requirements (*a*) the salines and (*b*) castor oil (in infants, sweet oil). Among the salines there is a wide range for selection, the phosphate of soda and the sulphate of magnesia being those most generally used, or, where the patient has been accustomed to use one of the saline aperient waters, this may be given, as the necessary dose is more readily determined.

My preference is for small doses of castor oil, just sufficient to cause one or two soft movements a day. I usually administer it in elastic capsules giving one or two drams at night and also in the morning if needed. If there is a tendency to griping the addition of three to five drops of chloroform to the capsules usually prevents it. When an intestinal disinfectant is needed five grains of salol may be added to each capsule. The form of cathartic and the dose should be that best suited to the individual case. It should be given throughout the disease for cleansing purposes only.

Intestinal Antiseptics.—Before the specific cause of typhoid fever was known, various forms of treatment, based on the intestinal lesions and considered more or less specific, were advocated. The two most important plans were the eliminative, by the use of purgative medicines, etc., and the antiseptic or germicidal, and frequently these two were combined in one as by the use of calomel.

Nearly every drug with antiseptic or germicidal action has at some time been used as a specific against the supposed infectious condition in the intestine. If, in addition to its antiseptic properties, the drug was also antipyretic, its advocates were the more numerous. After a more or less ephemeral reputation, most of these drugs have fallen into disuse. Those which have had a more lasting use are salol, bismuth, the salicylates and beta-naphthol.

Although typhoid fever is a bacillemia and it is futile to attempt to combat the disease by the use of intestinal antiseptics, still, changes in the intestinal contents and bacteria and secondary changes in the intestine itself may call for specific antiseptic treatment. Putrefaction or fermentation of the intestinal contents may induce inflammatory changes in the bowels, or, through systemic intoxication, cause an increased susceptibility to reinfection by the typhoid bacillus, giving a recrudescence or relapse. Alessi, in the Hygienic Institute at Rome, found that rabbits, guinea-pigs and rats lost their natural immunity to typhoid fever when poisoned by an atmosphere vitiated by emanations from a privy-vault or collections of their own excreta.

When systemic intoxication occurs through absorption from the intestine, the susceptibility of the patient to reinfection is greatly increased and many cases of relapse have been traced to this cause. In combating putrefactive changes, personally I prefer salol, either given alone or dissolved in castor oil as mentioned above. If salol is not tolerated then the salicylate of bismuth (5 to 10 grains) may be used. Recently a new intestinal antiseptic, acetozone (benzoyl-acetyl-peroxide) had appeared and even specific action is claimed for it. When administered during the entire cause of the fever it is claimed (*a*) that the length of the disease is lessened, (*b*) the stools and also hospital wards that contain a large number of typhoid fever patients lose their characteristic odor, (*c*) diarrhea and tympanites are checked, (*d*) stupor and delirium are very much less, (*e*) the temperature runs a lower course and hyperpyrexia but rarely occurs. It is said that relapses are infrequent when its use is continued until convalescence is established, also that it does not affect deleteriously the heart, lungs or kidneys. Whether these claims will be substantiated, time alone will tell. Personal use in a limited number of cases who could take the drug in the quantities and for the length of time advised has not given such encouraging results.

With attention to the diet and with thorough cleansing of the bowels the use of the different intestinal antiseptics has less place in typhoid therapy than heretofore.

Management of the Temperature.—The control of the temperature has always been considered one of the prime objects in the treatment of typhoid fever. The fact is often lost sight of that it is not the degree of fever that should guide us in the administration of antipyretic treatment, but rather the associated symptoms showing the action of the toxins on the nervous system and metabolism, *i.e.*, stupor, delirium, cardiac, respiratory and gastro-intestinal disturbance, emaciation and especially the condition of the urine. Any treatment that merely reduces the temperature but does not improve these associated conditions is useless or harmful.

Hydrotherapy is the method most commonly used to reduce the temperature and by many it is considered the only means that is justiable. In hospitals and frequently in private practice, antipyretic baths are ordered whenever the temperature rises above 102.5° F.

It is unnecessary to describe the different varieties of baths and their administration. It is only necessary to call attention to the fact that their use is twofold—first the extraction of heat, and second the toning up of the nervous system. In order to obtain the first-mentioned effect it is necessary for the surface circulation to be active. If cold is applied and there is no reaction of the surface circulation there will be diminished heat elimination through the contraction of the capillaries and also increased metabolism. It is therefore necessary, by brisk rubbing, to ensure an active capillary circulation. When this is obtained then the full tub-bath, the mitten bath, the bed bath, etc. will give satisfactory results according to the individual susceptibility of the patient and the degree of fever.

The routine practice of tubbing the patient

whenever the temperature reaches 102° to 103° F. is rapidly falling into disuse and the need of rest and of conserving the energy of the patient is being more and more considered in relation to the bath treatment. Rarely is it necessary to give a patient more than three, or at most four or five baths a day. The individual susceptibility should always be tested by having the first bath at a temperature of about 90°. In many cases where the cold bath of 70° to 75° F. causes profound shock, better results can be obtained by the warm bath, which, according to the plan of Liebermeister, may be gradually cooled.

At the present time the use of the coal-tar antipyretics and quinine is deprecated by most authors in the treatment of typhoid fever. The antagonism to these antipyretic drugs is largely the result of excessive use when the antipyrine group was first introduced into medicine. When given in large doses so as to depress the temperature to normal or below, they undoubtedly do great harm, but when combined with the bath treatment they have the power of controlling the temperature and at the same time improving the general condition of the patient. Phenacetine given in small doses does not cause dangerous depression of the heart, but on the other hand has the power to reduce temperature through its action upon the heat-regulating nervous mechanism so that the point at which the temperature is maintained is a lower one. The drug counteracts the effect of the toxins on the heat-regulating apparatus, and as a result, of even the temporary lowering of the temperature the proteid waste is limited and nutrition conserved. Acetanilid is preferred by many to phenacetin but on account of its tendency to cause cyanosis in some individuals it should be used with caution, unless the patient's tolerance is known.

Quinine has always held its reputation among clinicians as an antipyretic. Recent investigations have shown that its action is not upon the heat-regulating apparatus, as is the case in the coal-tar series, but rather that it has the distinct power of controlling nitrogenous metabolism, so that the old name of "fever food" is still applicable to the drug. When given for its antipyretic effect the full dose (15 grains) should be given at once, or 5-grain doses repeated every fifteen minutes until the full dose is taken. The heroic doses of 30 to 40 grains are rarely necessary or justifiable, although at times cases do occur in which this amount must be given in order to positively control the temperature. After the initial dose of fifteen grains has been given the antipyretic action may be continued by giving 5-grain doses at three or four hour intervals. Quinine is especially indicated as an antipyretic in the so-called cases of posttyphoidal sepsis, where the temperature is due, not so much to the acute typhoid infection as to a septic infection from the ulcerated intestinal wall.

Cardiac Stimulants.—Progressive cardiac weakness is one of the most alarming features of typhoid fever. Early in the disease physical examination shows increase in the area of cardiac dulness, the apex beat becomes indistinct, there is diminution in the intensity of the first sound with relative accentuation of the aortic second sound and absolute accentuation of the pulmonic second sound. These evidences of myocardial weakness usually increase in intensity up to the third week, or, if convalescence is delayed, may go beyond this and be the determining cause of death. Although myocardial weakness is present the pulse is usually slower than in other febrile conditions and the pulse curve will not be found to run parallel with that of the temperature.

The changes in the myocardium and in the pulse during the early stage of the disease are undoubtedly due to the specific action of a toxin on the nervo-muscular mechanism of the circulatory system. In addition to these cardiac changes we frequently meet instances of sudden collapse designated by the term "acute cardiac failure." Romberg has lately shown that in other infectious diseases than typhoid fever this acute cardiac weakness is due to the effect of a toxin upon the vasomotor system.

The conservation of cardiac energy has always been one of the most important objects in the treatment. During the early period of the disease our efforts are directed to the free elimination of the toxins and the fortification of the nervous system against their action. The free elimination of the toxins is best secured through the kidneys by giving the necessary quantity of pure water. When the function of the kidneys is impaired the use of diuretin or agurin not only increases their eliminative power, but at the same time acts as a cardiac and cerebral stimulant.

Against the action of the toxin on the heart and nervous system, two agents have been especially advocated, viz., strychnine and alcohol. At the present time strychnine is the more commonly used and I cannot too strongly dissent from the present plan of giving strychnine in heroic doses as soon as typhoid fever is diagnosed. It is not unusual to find, both in hospital and private practice, patients who have gone through the first week or ten days of typhoid fever so freely drugged with strychnine that their reflexes are exaggerated. In these cases much of the restlessness and distress, supposed to be due to the disease, is actually caused by medication. Patients who are early stimulated to the full physiological limit by strychnine make a slower convalescence and are more prone to vasomotor disturbance and nervous depression during this stage. Strychnine should be reserved until the condition of the reflexes, both cardiac and spinal, show that the disease has begun to affect nervous centers and its dose should then be regulated so as just to meet the indications.

Among older clinicians alcohol has always been considered a sheet-anchor in the treatment of this disease, but in recent years its value as a cardiac stimulant has been doubted and pharmaco-

logical experiments and data have been brought forward to strengthen this contention.

Although alcohol in the animal and in the healthy individual may show no action upon the circulatory system beyond a reflex one, still in diseased conditions, especially the infectious fevers, it has a different action. We are all familiar with the fact that large doses can be given to a febrile case without symptoms of intoxication being induced or the odor of alcohol appearing on the breath, and that under its use the nervous system is quieted and cardiac action slowed, while the respirations are fuller and deeper. Whether in health alcohol acts as a food, is not germain to this discussion—certainly in typhoid fever alcohol acts both as a stimulant and a food, and when the diet is deficient, as when a milk diet alone is given, nutrition is improved and emaciation retarded.

I do not advise the giving of large quantities of alcohol throughout the entire course of the disease, but where the patient is steadily wasting and where there is evidence of progressive cardiac weakness, alcohol should be used to combat this condition. If the beneficial effects are obtained with a few initial doses its use should be continued; if, on the other hand, the patient becomes more restless and the pulse quicker, then its use is contraindicated. In young persons especially its early effects should be watched.

Another drug that is abused in the treatment of this disease is nitroglycerin. Frequently in acute collapse, or when cardiac weakness has reached the point of causing the pulse to become dicrotic, this drug is given at frequent intervals with the idea of diminishing the work of the heart. In acute cardiac collapse Romberg has shown that there is already vasomotor paralysis and that the failure is more vascular than cardiac and nitroglycerin cannot under these circumstances relieve the condition. In the later stages of the disease when the pulse is dicrotic, the dicrotism is due to the relaxed condition of the arteries, and the giving of nitroglycerin does not relieve the heart, but, on the other hand, destroys the normal control of the circulatory system. Nitroglycerin should only be given when arterial tension is relatively too high for the cardiac power and then only to carry the patient over the immediate danger. It is not a drug that should be given continuously for any length of time.

I have already exceeded the time allotted for this portion of the symposium, and it is impossible to consider in the limit set for this paper the treatment of all the conditions and complications that may arise during the course of typhoid fever. I have tried merely to emphasize that the treatment of typhoid fever, whether dietetic, medicinal or hydrotherapic, is apt to be too routine and to show too little individualization. Many fail to meet the most positive therapeutic indications because the case is one of typhoid fever and they fear to depart from the orthodox methods of treatment. There should be no hard and fast treatment of typhoid fever. The therapeutic problems presented by each case should be met with the same medical judgment that is used in the treatment of other diseases.

THOUGHTS ON CHLORINE AND AN ANTISEPTIC TECHNIC.*

BY DOUGLAS H. STEWART, M.D.,
OF NEW YORK.

THE preparation of this simple preliminary paper has been most difficult. A bacteriologist, an obstetrician and three surgeons have asked me to meet the following tests:

First.—It makes no impression if you never get a culture from your hands. Show me what you can do with anthrax.

Second.—Results with anthrax are valueless. Few surgeons have met it, none have contaminated wounds with it, and only hand results appeal to us.

Third.—Do not give us any results with any chemical. The profession has gone chemically mad.

Fourth.—Your technic does not make the hands dry enough.

Fifth.—It makes the hands too dry.

These opinions, given by men of reputation, ensure failure for the writer unless all that he says is verified by many observers. Let us consider one germicide, chlorine; one standard, 1-1,000 bichloride: one test germ, anthrax, and one medium, nutrient agar. Cultures spoken of as positive have grown, as negative have not grown. Many men have found that fresh aq. chlori. (.4 per cent.) would destroy anthrax in a day. Geppert says anthrax spores may be active after an immersion of twenty-five hours in 1-100 bichloride. I have taken twenty-five successive positives after a ten-minute exposure to 1-1,000 bichloride. After one-per-cent. lysol I have never failed to obtain positives, yet this soap is a powerful antizymotic and arrested the action of yeast and pepsin. One technic, glycerin and calx chlorate, fizzed but did not explode possibly because the hands were plunged instantly into cold water. Contact was not over fifteen to twenty seconds but it blistered badly wherever it touched my skin.

The two best known chlorine solutions are the liq. sod. chlorat. of Labarraque and the liq. pot. chlorat. of Javelle (Javelle is a mill, not a man, by the way). Though the formulæ are quite different, it is doubtful if a druggist in our city is not selling both under a Javelle label.

By omitting water from the Labarraque we obtain the well-known technic of washing soda and calx. This with anthrax gave six positives out of six trials. It worked well against molds, gave quite as good results and did not attack the hands so much when one third (by weight) of the carbonat. potas. was substituted for the carbonat. sodæ. By modification this became calx, table

* Read before the West End Medical Society, Nov. 7, 1903.

salt, carbonat. potas. and aq. ammonia—one teaspoonful of the salts and four of the aq. It is irritating in proportion to the temperature of the quart of water in which it is dissolved.

During experimentation Javelle water was changed to one teaspoonful of sulphuric acid, of calx and of table salt. Ultimately this solution was divided into two of a pint each with the acid and lime in different basins. Just here several physicians expressed fears of the portability of the vitriol. Therefore another chlorine technic was worked out with acetic acid.

After testing many soaps the ordinary brown laundry variety seemed always sterile, but sterility of the hands from the use of any soap I have never seen. If green soap is ever sterile, then I have been unfortunate in my specimens, since every trial has given positives. Anthrax and molds grow in it.

Should you wish to eliminate soap from your present technic the following suggestion may be of some value. Take a heaping teaspoonful of calc. chlorat., of table salt and of aq. ammoniæ, mix them in a quart of cool water, bleach and cleanse your hands therein and they will often be sterile. Give special attention to the nails with powdered pumice, stick and brush. If you cannot make them macroscopically clean put chlorinated lime under them and around their margins.

Do not put the calx on the sensitive skin. When properly performed, you should not get more than two positives out of twelve attempts, although this washing is merely preparatory. One doctor, after a long railway journey gave one single spot in a Petri dish out of twelve trials. Several others have done as well.

At the Polyclinic Hospital the following method has been in use for the past fortnight: five minutes mechanical—pumice, brush, hot water, green soap and wooden nail cleaners. Five minutes chemical.—Two heaping teaspoonfuls of fresh calx chlorat. and one teaspoonful of U. S. P. acetic acid to the pint of sterile water. The germicidal power of this mixture fully equals 1-1,000 bichloride. On its best field of operation, *i.e.*, glassware, bichloride gave 56 positives and 34 negatives out of 90 tests while the solution gave 64 positives and 98 negatives out of 162. Tap-water was the solvent and anthrax the standard, while the conditions were kept as nearly identical as possible. On the hands my results with bichloride show so poorly that I prefer to make more experiments before pronouncing on its value. Septic wounds do surprisingly well with the chlorinated solution diluted with water (1 to 3 or 1 to 6) and applied on compresses. A weaker solution with prolonged contact is very effective.

An obstetrician should have an antiseptic hand, because of the very temporary duration of asepsis. A pair of rubber gloves were boiled hard for 15 minutes, laid on a sterile plate and exposed to ordinary conditions. Two tests were made every three minutes. The second trial of one glove, *i.e.*, at the end of three minutes, both tests were positive. The other glove took at twenty-one and twenty-four minutes. My left hand rendered antiseptic was absolutely negative up to 36 minutes when the test ceased.

One would think that a hand once antiseptic could be kept in that condition indefinitely. Out of eight attempts at complete hand-antisepsis for twenty-four hours three gave positives and five negatives. Of six attempts at five-hour antisepsis two gave positives and four negatives. The surgeon has a most valuable expedient in using one knife for the skin and another for the deeper parts. The obstetrician must get at his work through a contaminated ring. He deals with a septic finger, a septic vulva and an aseptic vagina —broadly speaking. No matter how sterile his glove the introduction of one finger will carry the germs of the vulva into the ostium vaginæ and may contaminate the whole tract. Obviously his only method should be to sterilize the vulva first, and then leave the vagina alone.

I know of no methods in general use which will sterilize a vulva. All fail when tried at the bar of the culture media. After sterilizing three different vulvæ I explained to Dr. Brodhead the *modus operandi*—he has experimented further and has kindly consented to discuss this part of the subject.

A pleasant surprise is the thermometric reading when the full technic for patient and attendant has been carried out. Recently my advice to pregnant women is to daily wash the mons veneris and all about the private parts with water 2 quarts, a heaping teaspoonful of calx, of salt and a half teaspoonful of pot. carb. Let it dry on the skin. The proportions should be reduced if any irritation is complained of, but as yet there have been no complaints save only from the heat of the water—this is better mixed hot and then allowed to cool. Without being too positive with but three vulvæ, one was sterile after the second washing, one after the sixth and the third was confined too soon to give any line. The difference in the cultures before washing and after was marked in every instance. The growths were slowed down. Three contrast (check) cases reached a maximum temperature of 100° F. during the puerperium. The three mentioned reached 99⅕° F. in one instance and 99° F. in the other two.

It may seem absurd, but I wish to emphasize that an antiseptic hand cannot be obtained by wiggling the fingers in any solution. The question of contamination must be answered by the culture process. P. D. Co. and the Board of Health put up little Löffler serum tubes and with care two culture strokes may be made in each one. A before and after test, if you wish; side by side. These can be incubated in the inside vest pocket. The P. D. tubes have rubber tips but those of the Board of Health should be sealed with wax. While the method is crude it gives fair results and may be the means of converting many from their pet technic. If any one should come

to the conclusion that the suggestions of the writer are worthy of trial then, to obtain good results fresh calc. chlorat. must be secured and it must be kept in small air tight glass or metal packages which are only opened when in actual use.

Finally, it is a well-known and commonly disregarded fact that all chlorine solutions depreciate very rapidly. In my experiments an active germicide effect of two-minute exposure was diminished to a five-minute one in a half hour and an eighteen-minute one in a day. After that it remained stationary for a time.

Note.—Dr. Brodhead reports only 5 positives out of 74 attempts at sterilization of the vulva.

121 West Eighty-eighth Street.

EXCISION OF THE FRENUM PREPUTII FOLLOWING LACERATION DURING A SUSPICIOUS INTERCOURSE.

BY CHARLES C. MILLER, M.D.,

OF CHICAGO.

IN this article I propose to recommend, as an addition to circumcision, a thorough removal of the remains of the frenum preputii, when this part has been distinctly lacerated or torn across during an intercourse with a woman who is likely to have been syphilitic.

By this operation, practised within twenty-four or forty-eight hours after the occurrence of the laceration and infection, it is hoped that infection

Fig. 1.

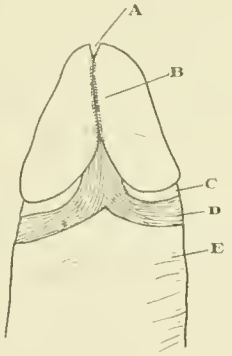

Fig. 1 shows penis after skin of prepuce has been cut away and mucous membrane trimmed. A represents meatus; B, remains of torn frenum; C, mucous membrane; D, raw surface between skin and mucous membrane; E, skin of penis.

with syphilis, where it has occurred, will be prevented from becoming constitutional.

If only one per cent. of cases are saved from syphilitic infection, by this simple procedure, we will have rendered that individual saved from infection an inestimable service, and, at the same time, no harm has been done to any upon whom the operation has been practised.

Note.—The illustrations are diagrammatic and all show line of frenum as longer than it really is in normal state.

Syphilis is an exceedingly common disease, and a very large per cent. of women submitting to illicit intercourse are syphilitic. In view of this, a laceration upon an unprotected penis during an illicit intercourse will in many cases subsequently mark the site of a chancre.

A great majority of patients contracting syphilis are never cured of the disease. This is usually

Fig. 2.

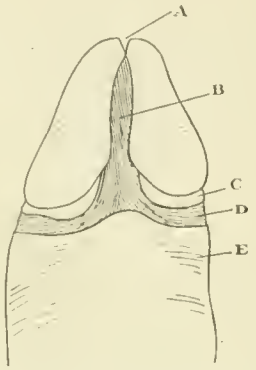

Fig. 2 shows groove made by scissors in excising remains of frenum. This is to be closed by a continuous suture of fine catgut before the sutures used in approximating skin and mucosa are placed. Bleeding of the parts will be controlled by the close continuous suture.

due to indisposition or inability of the patient to submit to prolonged skilful treatment.

Any measure which gives promise of preventing the development of syphilis, deserves a faithful trial until proved useless.

The course of syphilis makes it reasonable to suppose that constitutional infection may not occur for a number of hours at least after inoculation of the virus upon a raw surface.

Syphilitic infection is supposed to always occur through a break in the epithelial covering of the body. The frenum is a frequent site for the occurrence of abrasions or lacerations, as the result of violence during intercourse. Where this delicate bridle of tissue is completely torn across, atrophy will occur subsequently. As the part will disappear and functionate no longer, we are justified in hastening this somewhat by operation, if thereby we can save any of these cases from developing syphilis.

It is a disputed question, whether the mere presence of a redundant prepuce is sufficient ground for recommending its removal. Where the possessor of a redundant prepuce is exposing himself to infection by illicit intercourse, we are justified in advising the operation as a prophylactic measure, as by its removal we minimize the dangers of subsequent venereal infection.

If a patient consult for advice regarding a lacerated frenum, and he possesses a redundant prepuce, we are justified in advising circumcision, where the intercourse has been with some public woman, and as a further step to prevent the development of a possible chancre at the site of the frenum, it should be thoroughly excised during

the operation with a certain amount of the tissues upon each side and below as well.

In these cases the usual technic of amputating the prepuce will be followed. The skin is cut away along the line of the corona. The mucosa is now trimmed and hemostasis completed.

The cautery is to be used over the raw surface of the lacerated frenum in order that any surface

Fig. .

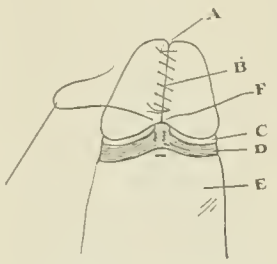

Fig. 3 shows groove formed by the excision of remains of frenum closed by continuous suture. F shows suture in place, which when tied will bring skin in contact with glans at former site of frenum. When this is tied operation concluded by approximating skin and mucosa around penis by a series of interrupted sutures.

infection be overcome before beginning the operation.

The frenum is to be extirpated with small curved scissors. This may be facilitated by drawing it out with tissue forceps. Such precautions are to be taken as are necessary to prevent contact of the lacerated surface of the frenum, with any raw surface to prevent any possible reinfection. The instruments used in this step of the operation are to be discarded until thoroughly sterilized.

Fig. 4.

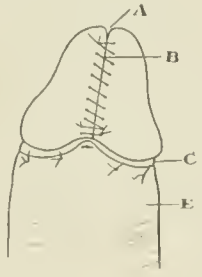

Fig. 4.—Operation complete. Groove left by excision of remains of frenum, closed by continuous suture and the mucosa and skin of penis approximated by interrupted suture.

As a result of our excision, in place of the remains of the lacerated frenum, we will have a groove about an eighth of an inch deep and somewhat wider. Beginning now near the meatus a continuous catgut suture is to be used closely approximate to the edges of the groove. A stitch is now placed so as to draw the skin forward in contact with the glans in the median line, and then the operation of circumcision completed in the usual manner.

Where the prepuce is not inflamed, the operation can be done with local anesthesia from cocaine. By carrying the needle along under the frenum, we can render the parts insensitive so that the frenum can be excised without pain.

A free oozing will commence as soon as we cut away the frenum. This will be controlled by the close continuous suture. If a needle with a cutting edge be used for the suturing through the glans, we will have a temporary hemorrhage from each needle puncture. No attention need be given to this as it will check of its own accord before the operation has been completed.

This procedure adds from three to five minutes to the length of time required for a circumcision, but it is easily performed without pain to the patient, and is not followed by any unpleasant complications or sequelæ.

The groove in the glans unites even more rapidly than skin and mucosa. Where plain number one catgut is used as a suture material, no further attention is required from this part of the operation, it coming away in a few days leaving the parts healed.

During a period of a little over two years, I have extirpated the frenum in this way five times. In only one case have there been any subsequent complications. In this, the first case, the tissues were cut away very sparingly forty-eight hours after the infection of the laceration. A portion was left and a chancroidal infection developed. This was healed without much difficulty with a perfectly satisfactory final result. It illustrated the need of a careful and free excision of the tissues. None of the other cases have developed a venereal sore at the site of the operation, nor symptoms of syphilis subsequently.

If the operation prevents one per cent. of cases from developing a constitutional syphilis, it will prove a valuable addition to the operation of circumcision in those cases.

CHICKENPOX CONCURRENT WITH SMALLPOX.

BY PHILIP D. BOURLAND, M.D.,
OF LAKE LINDEN, MICH.;
SURGEON TO THE CALUMET AND HECLA MINING COMPANY.

Comparatively little has been written upon this subject, notwithstanding the fact that within the last three years varicella and variola have had unusual opportunities to present themselves simultaneously, owing to the wide distribution of variola.

It is conceded that varicella and variola are distinct diseases, yet their points of resemblance make their association interesting and worth study. Among the few who still affirm the unity of the two diseases are men of reputation, which fact, in connection with our ignorance of the specific cause of chickenpox, at least, and the difficulties of differential diagnosis occasionally met with, lends additional interest to the subject.

The views of the dissenters have been fully quoted by J. S. Schamberg and need not be recon-

sidered. It is not my purpose to argue this matter, but to proceed upon the supposition that the identity of the disease with which I dealt is doubtful, and to attempt to justify a diagnosis of chickenpox in my cases, at a time when smallpox was rife, and its importance deeply impressed upon the public mind.

The prevalence of smallpox in Houghton County for nearly three years, and of chickenpox during a part of that time, has furnished an unusual opportunity for a study of these diseases in concurrence. Variola prevailed mainly in Calumet, including the contiguous villages Laurium and Red Jacket, and in Houghton and Hancock and their environs, and varicella mainly in Lake Linden, distant five miles from Calumet and twelve from Houghton and Hancock. Free communication between the various towns existed at all times, however, and abundant opportunity was afforded for carrying disease from place to place.

I have not been able to ascertain the total number of smallpox cases in the recent epidemic, but an idea of its prevalence may be had from the figures furnished me by Mr. Robert Wetzel, health officer of the Calumet district. There were reported between the dates May 31, 1900, and December 3, 1902, 106 cases. The remainder of the county may be supposed, without great error, to bring the total to four or five hundred cases. Fully 75 per cent. of those in Calumet were adults. The epidemic was a mild one, not over four deaths resulting, a mortality of about one per cent. What percentage of cases were confluent I have not been able to find out. It may be said that the cases presented, as a rule, the classical picture of a mild type of variola.

In Lake Linden and South Lake Linden, there were probably not more than a dozen cases of smallpox throughout the entire epidemic. In this district, however, varicella was especially prevalent from the fall of 1901 to the following spring, fully 100 cases occurring in my practice alone. At the time of the outbreak of the varicella epidemic there were, to the best of my knowledge, no cases of variola in those two towns. A few cases appeared later, in the summer of 1902, and some had existed previous to the varicella.

On November 20, 1901, I found a case of varicella in South Lake Linden. On inquiry, I found that there had been other cases among the schoolmates and playmates of my patient; cases which no physician had been called to attend. Some of these children attended the German Catholic School in Lake Linden. This school had an attendance of 150 children from six to fourteen years old. On December 7 varicella appeared in this school and soon became widespread throughout its membership, but was restricted, in Lake Linden, to this school. In South Lake Linden, where some of the pupils lived, numerous cases developed also.

To show how closely the spread of the affection was limited, I can say that I was not called on to treat a case outside of the German School pupils or members of their families, until January 11, 1902.

Careful record was kept of 29 of the earlier cases. In each instance there were two or more children in the infected families, and in the absence of protection by previous attack, nearly all those of an easily infected age became infected. Those not yielding to infection were usually over twelve years old. One child of eight, who had had varicella at three, had it a second time.

The ages of my patients varied from nine months to fifteen years. By periods of five years the table is as follows:

Under 1 year,.....	2 cases.
From 1 to 5 years inclusive,.....	11 cases.
From 6 to 10 years inclusive,....	13 cases.
From 11 to 15 years inclusive,....	3 cases.

To sum up:

Total number of children in infected families, ...	53
Number of cases,.....	29
Protected by previous attack,.....	8
Infected notwithstanding previous attack,	1
Not yielding to infection, though not protected by previous attack,.....	16

The ages of these last were, as I have elsewhere stated, usually more than twelve years.

Thirteen of the 29 had been vaccinated within the preceding two years. Eleven of the vaccinations were said to have taken, though scars were not always found to corroborate the statements. The remaining 16 had never been vaccinated.

Regarding the vaccination of the parents of these children my data are meager. In four instances both parents had been successfully vaccinated in early life, at such an interval that the vaccination could no longer be considered protective. My impression is, that the remaining nine pairs were not vaccinated. None of the exposed adults had ever had variola, and none yielded to the varicella infection, if we exclude a girl of fifteen, my oldest patient.

In studying the incubation period, a number of points must be remembered. First: several children of the same family, attending the same school, and undergoing the same exposure, would develop the disease within a few days of each other. In such cases, the first child becoming sick cannot be supposed to have infected the others, nor can in any way, the time of incubation be definitely settled.

It is only in those cases where children too young to go out of doors, or to play indiscriminately with other children, contracted the disease from their older brothers and sisters, that the incubation period can be determined with any accuracy. In twelve such instances the period varied from eight to sixteen days, the average being between eleven and twelve days. A prodromal stage of a few days, was noted in several cases, with malaise and anorexia as symptoms. There were sometimes no symptoms of onset, the parents, attention being first drawn to lesions on

the face. In very young children fretfulness, anorexia, itching, and fever ushered in the sickness. The older children presented various combinations of the following symptoms,—headache, usually frontal, and not severe, dizziness, moderate lumbar pain, anorexia, chilliness, nausea, sore throat, and itching. Excluding the cases without symptoms, anorexia, chilliness, sore throat and itching were universal.

Objectively, fever not higher than 101.5° F. was noted, usually it did not exceed 100.5. Congestion of the pharynx fauces and palate was present in nearly all cases, and was accompanied by lesions of the mucous membrane.

The skin lesions always appeared within thirty-six hours, usually within twenty-four. There was in no case any preliminary scarlatiniform rash. The lesions were invariably discrete and the unaffected skin was not red.

As a rule they first appeared on the trunk, generally selecting the back, and soon after coming out on the chest. The back was usually more thickly covered than any other region. The forehead, temple, back of neck, postauricular region, axilla, arms and legs were also cited as localities of first appearance of lesions in a few instances. Frequently the disease was unnoticed till the lesions appeared on the face, when an examination would show that they had existed for some time on the trunk and limbs. In such cases the oldest lesions were usually found on the back. The spread of the rash was always rapid, full eruption always occurring in from twelve to twenty-four hours, and occasionally in six hours. The lesions were numerous, and widely distributed. The scalp, forehead, temples, eyelids, the lower parts of the cheeks, chin, postauricular regions, neck, back, chest, axillæ, arms, forearms, wrists, dorsal and palmar surfaces of the hands, the fingers, the abdomen, buttocks, inner surfaces of thighs, legs and feet, were attacked, and the pharynx, fauces and hard palate very frequently showed lesions, while the soft palate and tongue only occasionally presented them. The lesions of the mucous membranes were accompanied by a diffuse congestion out of all proportion to the redness circumscribing the cutaneous lesions.

Of the skin surfaces, the back, chest, scalp, and some portion of the face, usually the forehead, were involved in all cases, the back being the scene of the most numerous lesions. The arms, forearms and wrists were attacked next in frequency, then the thighs and legs. No preference was shown for flexor or extensor surfaces. The palms and back of the hands were involved in several cases, and in one instance, a finger. The feet and toes were rarely affected.

The lesions always began as small, thinly covered, red, raised papules, involving only the superficial layers of the skin. Induration was very slight or absent. There was no shotty feel. Slight hyperemia was always present, the papule being encircled by a narrow zone of congestion. The papules were usually tender on pressure. Within a few hours, the papules began to vesiculate. The vesicles were small, thin, and at first clear or pearly. Their average diameter was 1 to 2 mm. but occasionally they were larger, 2, 4 or even 5 mm. in diameter. In a case of varicella bullosa, some vesicles measured 8 mm. and over. On the second or third day, the vesicles became turbid, and at this stage, not only flattening, but very often more or less umbilication was observed. The shriveling of the vesicles now began and progressed rapidly till in four or five days, sometimes only three, from the beginning of vesiculation, crusts varying in color from yellow brown to chocolate, and surrounded by a narrow zone of congestion, were all that remained. In a number of instances it was noted that clear vesicles became turbid, brownish and shriveled within twenty-four hours. As the papules were vesiculating, fresh crops appeared, to be followed in turn by others till the disease was spent, so that, by the third or fourth day, lesions were present in all stages from papules to drying vesicles.

At the end of a week, or sometimes at the end of five days, all lesions were drying, and the crusts of the earlier ones loosening. The crusts of the last crop did not fall for from ten to fifteen days. The greatest persistence was shown by the scalp lesions. There was no scar unless scratching had been indulged in, with resulting infection. A very faint light brown stain occasionally remained, for only a short time, however. The fever did not decline with appearance of the eruption, but persisted, as a rule, till by the absence of further crops of papules and by drying of the older lesions, the disease showed that it was declining. There was in no case any secondary fever. Instead of a rise as the vesicles became turbid, there was a tendency toward a fall of temperature.

An interesting symptom, which I have not seen described, is enlargement and tenderness of the occipital glands. Of my 20 cases, these glands were affected in 16; both sides 10 times, the right alone five times, and the left alone, once.

The enlargement and tenderness began from one to three days after the onset, and persisted, in some instances for three weeks, usually however subsiding with the decline of the disease. There were no complications, sequelæ or deaths among my cases.

The description just concluded corresponds in nearly every detail with that of chickenpox. I have reported vesicles on the forearms, hands and fingers in several cases, which is not usual in chickenpox, but which by no means excludes that affection. Wanklyn (an English writer) says that the freedom of the hands and forearms in varicella, as compared with smallpox, is remarkable, but that we cannot exclude varicella if vesicles occur on the hands and feet. It is the relative distribution that is to be emphasized.

Differential diagnosis was, as a rule, easy. The more severe cases occasionally made me reserve my decision for a day, but usually attention to the following points, made the diagnosis clear: (1) Mild onset; (2) absence of preliminary rash; (3) rapid appearance of eruption; (4) failure of

temperature to decline with appearance of eruption; (5) distribution of lesions; (6) character of lesions; (7) rapid vesiculation; (8) successive crops of papules; (9) absence of secondary fever; (10) short course of disease.

I cannot speak from personal experience of the blood picture of varicella and variola, nor of the microscopical appearance of the vesicular fluid as described by Professor Courmont of Lyons.

In concluding my analysis of the epidemic described as chickenpox, I would emphasize the following points:

1. The concurrence of smallpox in no way caused the course of my cases to depart from that typical of chickenpox.

2. Vaccinated and unvaccinated children showed equal susceptibility to infection, and the course of the sickness was the same in each class. This fact excludes varioloid.

3. None of my patients had ever been exposed to smallpox or had ever had it.

4. No adults were attacked notwithstanding absence of vaccination in a majority.

5. Five of the children exposed had had chickenpox in a previous epidemic, these previous attacks conferring immunity except in one instance.

6. Smallpox and chickenpox are distinct pathological entities, and though in intimate association, neither disease influences in any way the natural history of the other.

SPECIAL ARTICLE.

MORBID ANATOMY AND HISTOLOGY OF PULMONARY TUBERCULOSIS IN RELATION TO ITS GENERAL PATHOLOGY AND CLINICAL MANIFESTATIONS.*

BY G. SIMS WOODHEAD, M.A., M.D.,

PROFESSOR OF PATHOLOGY IN THE UNIVERSITY OF CAMBRIDGE, ENGLAND.

WHEN the Henry Phipps Institute for the Study, Treatment, and Prevention of Tuberculosis did me the honor to invite me to give one of this series of lectures, I felt that I had little time in which to prepare any lecture worthy of the occasion. I was just in the midst of the work of our term, and as I had to start for your shores as soon as the term ended, I knew that until I got onto the Atlantic (whose vagaries at this time of the year have to be reckoned with) I should be able to give but little time or attention to the thinking out of the details of my address.

The opportunity of visiting your great country thus presented to me was, however, so tempting and the prospect of meeting my many valued friends on this side so attractive that I determined to give you the results of some of my own work on the relation of the morbid anatomy and histology of phthisis to its general pathology and clinical manifestations. I was all the more tempted to follow this line of thought from the fact that in recent years the pessimistic views of the physician—based on the pessimistic foundation laid by the earlier pathologists—though gradually giving way before the evidence afforded by more recent research are hard to scotch and still more difficult to kill. It will, of course, be understood that the advancing and advanced lesions found in cases of pulmonary tuberculosis that had succumbed could not but prove fatal. The presence of Virchow's caseous tubercle in all its fearful and destructive simplicity seemed to leave no hope for the recovery of any patient affected; and what the pathologist found one day the physician accepted the next. It was perhaps natural that this should be the case but the evil wrought by this pessimism was incalculable and I think that most of those of you here to-night, who have given even a small amount of attention to the subject will agree with me that this view as to the incurability of tuberculosis had more influence than any other single factor with which we are at present acquainted, in interfering with the successful treatment of a disease that should, I venture to say, now be looked upon as among the most curable—when taken early enough, treated under proper conditions, and for a sufficiently long period.

If modern pathology had been responsible for nothing beyond the effect that its findings have had on our ideas concerning the course of the tuberculous processes, especially in the lung, it would have more than justified its claim to be one of the most important, if not the most important, of all the sciences ancillary to medicine.

I am here to speak as a pathologist, and it is possible, nay, even probable, that some of you may be of opinion that I claim too much for my subject; but of this I am convinced—that the more closely the pathology (including morbid anatomy and histology as read in the light of recent bacteriological discoveries) of tuberculosis is studied in the cases that come under the observation of your physicians, the greater will be the influence of the work ultimately done in this Institute. The cure of the individual must, naturally, be the most pressing and important claim on all those engaging in this work, but it must be remembered that there are far wider reaching questions behind and beyond this—the early detection of the disease, if treatment is to be most successful; and the prevention of the disease, if the community is to derive the greatest benefit from the warfare now being carried on; and these must be worked out, not in the ward merely, but also in the side-room and in the laboratory.

I have said that it is only during recent years that much has been heard of the curability of pulmonary tuberculosis, but it must be borne in mind that after the first shock produced by the observations recorded by Rokitansky and by Vir-

*A lecture delivered under the auspices of the Phipps Institute, Philadelphia, Dec. 29, 1903.

chow had lost some of its force, a number of observers drew attention to the fact that in the lungs of old people who had succumbed to diseases other than those of tuberculous origin there could often be found local apical thickening of the pleura or, still more frequently, deeply pigmented irregular scars which were evidently the result of some considerable loss of tissue at an early period of life. My attention having been drawn to this fact, I took the opportunity, after I had been appointed pathologist to the Edinburgh Royal Infirmary, to make a careful search for evidence of what I might speak of as healed tuberculous lesions, and I found that in old people such evidence was to be found in at least one out of every three who came to the post-mortem table. Nay, more, I soon became firmly convinced that even in those cases that succumbed to tuberculous disease there was usually more or less marked evidence of a sturdy war waged by the tissues against the invading tuberculous process, and that in most cases the tissues failed in their endeavor to check the advancing process simply because they were placed under disadvantageous conditions, not as the result of the action of the specific *materies morbi*, but as the result of interference with their nutrition. The cod-liver oil treatment, so long the most successful of all, had its foundation in the belief that this substance served some special nutrient or therapeutic purpose, as a result of which the tissues were strengthened and were thus enabled to resist the attacks of the disease-producing factor; whilst the present-day treatment of tuberculosis is founded on a similar belief that fresh air, good food, efficient excretion of waste products, rest (opportunity for building up the tissues, food that will supply energy with least draft on the tissues), will enable these tissues to withstand the attacks of the disease-producing factor; while to kill it in the second, or at any rate to render it harmless; and finally to assist in the removal not only of the bacillus, but of the dead or degenerated tissue in which it had managed to effect a lodgment.

It is perhaps superfluous at this stage to show slides of the tubercle bacillus, but some few of you may not have seen these microbes—low vegetable parasites—so fully studied by Robert Koch in his epoch-making work sent out from the Royal and Imperial Institute of Public Health in Berlin. (A series of slides illustrating the form and relative size of the tubercle bacilli as found in experimentally produced tuberculosis, in the tuberculosis of the human subject, and in phthisical sputa were then thrown upon the screen.) For some time after the appearance of Koch's wonderfully lucid and convincing paper a certain number of skeptics,—perfectly justifiably, no doubt, on account of the extreme novelty of the ideas so promulgated,—attempted to throw doubt first on the accuracy of the observations and then on the reliability of his conclusions, but it may now be fairly claimed that Koch's work has, in the main, withstood the attacks even of the ablest of his critics. There seems to be no manner of doubt that we may accept Koch's tubercle bacillus as the *causa causans* of tuberculosis. Here, however, let me put you on your guard, as I guard myself, against a mistake into which it is very easy to fall; *i.e.*, that because a tubercle bacillus comes near, or even into contact with, the human or brute body, an attack of tuberculosis necessarily results. This bacillus must make its way not merely onto a free surface, but into the tissues of the body, before it can do any harm; nay, more, it seems that, in the human body at any rate, the tissues must be damaged or weakened and a special mode of entrance into these damaged tissues must be prepared for the tubercle bacillus before it can work its dire effects. During the course of my work my hands have for weeks, months, or even years, been almost daily soiled with tubercle bacilli; I have no doubt that I have swallowed many, and that some have made their way into my respiratory tract; but none of these has done me much, if any, harm because while I have been working with them I have carefully protected any cuts on my hands and have refrained from working when I have been run down in any way, and especially when I have been suffering from any catarrhal processes in the respiratory or alimentary tracts.

From my experiments on animals I am satisfied, as are all experimenters, that tuberculosis is never produced without the presence and action of the tubercle bacillus, but my own observations on human patients, especially on children, confirm those of many others, that unless the tissues are weakened or damaged—*i.e.*, the soil is prepared—there can be no reaction between the bacillus and the tissues which can end in the production of a tuberculous lesion. The exciting cause must be present, but in the human subject at any rate there must also be one or more predisposing causes. In the lung this predisposing cause appears to be catarrh; that is, a congestion of the vessels of the mucous membrane, accompanied by some slight proliferation of the epithelial cells lining the air vesicles, with an increased pouring out of fluid and an emigration of a larger number of white blood-cells. In the air vesicles of the lung, especially when expansion and contraction are weak or imperfect,—*i.e.*, at the pulmonary apices in adults, near the the root of the lung in children (and in monkeys), beneath areas of adhesion between the pulmonary and costal pleuræ, and at the base of the lung when there is adhesion of the pleuræ in this position especially if the liver be adherent to the under surface of the diaphragm,—there is usually an accumulation of catarrhal products in which if bacilli gain entrance and are allowed, undisturbed by any great amount of movement, to multiply, to produce their special products and to cause those degenerative changes with which they are found to be associated causally. Once give them a footing under these conditions, and they are in a favorable position to produce tuberculosis.

It is evident from what has already been said

that the tubercle bacillus may reach the lungs by way of the air-passages; that they make their way to those points at which there is least movement and in which, as a rule, there is some degree of collapse, often associated with a condition of catarrh —*i.e.*, a condition in which the protecting layer of epithelium has been damaged, the lung tissue then being in the same position as the hand on which the epithelium has been damaged. From this coign of vantage they may be distributed, still by the air channels, to almost every part of the lung, setting up a condition of tuberculous catarrhal pneumonia characteristic of the latter stages of the so-called acute phthisis. In many cases this acute phthisis is nothing but an acute secondary pneumonic tuberculosis following a rapid distribution of tubercle bacilli embedded in the caseous material derived from a chronic primary focus. It should be noted that in these cases caseation of the epithelial tissues usually takes place at an early stage of the process.

So much for the distribution by the air-passages. We now come to a second system of distributing or infection channels which appears to play a prominent part in every case of tuberculosis, chronic or acute—the lymphatic system. Between the cells of the tissues and especially around such structures as the blood-vessels, even the smallest of them, there is a kind of network of channels or spaces (the lymph spaces) that has sometimes been compared to the system of pores seen in a sponge. Such terminal spaces gradually lead into small definite channels and finally into tubes or vessels of considerable size and with distinct walls—the lymphatic vessels. These tubes lead to little filters known as lymphatic glands. Much of the fluid that in the process of nutrition passes from the blood-vessels passes into these lymphatic spaces, and from this fluid the tissues take up their nutrient material, throwing back into it their waste or effete products. The fluid throws some of these waste materials back into the blood, but certain of the more solid particles pass to the lymphatic vessels and by them are carried to the lymphatic glands, where the coarser particles are filtered out, and where, too, certain changes appear to be effected even in the composition of the fluid lymph.

Let me give you an illustration. If a patient tattooed on the forearm could be examined within a few days of the operation, small particles of pigment would be found in the tissues (cells in and lining the lymph spaces) at various points between the tattooed patch and the elbow, and even above the elbow. If the patient were to live for some months and then were to die, it would be found that, except at the tattooed patch and in some little hard nodules in front or at the side of the elbow or under the armpit, there is no pigment, but in these latter positions black, red, or blue pigment, according to the material used by the artist, has accumulated, often in quantities, so that it can be seen with the naked eye.

Most of you know how the glands under the arm swell after vaccination. This is because the lymphatics of the arm carry the vaccine virus to the glands, they are irritated by the vaccine matter, there is proliferation of cells, swelling of fibers, an accumulation of fluid, and enlargement of the whole gland.

Exactly the same arrangement of lymph spaces, lymph channels and lymphatic glands is met with in the lung. There are spaces around every vessel and bronchus and between the finer tissue elements; these open into lymph vessels which in turn convey the fluid to the lymphatic glands situated at the root of the lungs. It is important to bear this arrangement of the lymphatics in mind, for we find that in tuberculosis of the lung the tuberculous virus is carried from the air vesicles by the lymphatics to the lymphatic glands. The tubercle bacillus or its products appear to exert some irritant effect directly upon the cells lining the lymph spaces, as a result of which, just as in the air vesicles, we have a proliferation of the cells and a formation of new tissue sometimes resulting in caseation or the formation of a soft pultaceous mass which is supposed to resemble cheese; at others—and this is a point to be specially borne in mind—in the formation of fibrous tissue.

As regards this formation of fibrous tissue, it may be well to point out that the most marked feature in chronic tuberculosis is the formation of fibrous tissue in the pleura immediately above it; and it is an easy matter in most cases to determine roughly the comparative duration of the disease at any part of the lung by noting the thickness of the pleura and of the interlobular septa; so that in a chronic phthisis in which the patient succumbs rapidly as the result of an acute consolidation, there is usually well-marked thickening at the apex; this gradually shading off to the lower part of the upper lobe and being represented merely by a thin film of fibrin over the lower lobe.

Where the tuberculous process specially affects the adventitia or outer coat of the blood-vessels and bronchi this fibrous tissue formation is often exceedingly well marked. In some cases it would appear almost as though the tuberculous tissue at first of a type which may be compared to an irregular granulation tissue, may become converted into fibrous tissue directly; but it may be accepted as a general statement that where the tubercle bacillus manages to obtain a footing, it brings about a certain degree of caseation; but that in the immediate neighborhood of this caseous material, which in some sense appears to act as a foreign body, the fibrous tissue is partly at any rate the result of the action of this foreign body upon endothelial cells or connective tissue cells, which, after all, must be looked upon as cells of an endothelial type.

Wherever this fibrous tissue is formed, it affords evidence of a good reaction on the part of the tissues and therefore of the powers of resistance; it is by the formation of this fibrous tissue around the areas of caseation that they are cut off and the lesion localized. Where this localization

is incomplete, as it often is, the bacilli pass along by them to the lymphatic glands, here giving rise to proliferation, caseous degeneration or fibrous tissue formation, just as is the case along the lines of the lymphatics. Having once reached the glands at the root of the lung, the process may, for a time, be localized; but unless the conditions are favorable and what we may call the reaction of the tissues is good, the tuberculous virus may be carried from point to point, successive glands in the neighborhood localizing the disease for a time, but ultimately allowing of the passage of the virus to other organs.

In connection with the invasion of lymphatic glands by the tubercle bacillus, it should be noted that once a lymphatic gland is affected, the course of the lymph circulation may be diverted; and again that any area usually drained into a lymphatic gland becomes much more readily affected when that gland becomes tuberculous than before this takes place; I think I have seen cases in which the lymphatic gland appears to have become caseous or cheesy before the area drained by it had become tuberculous. It is somewhat difficult to prove this; but I show you a specimen in which we have an exact localization of a tuberculous area to that part apparently drained by a small gland at the root of the lung.

The third method of transportation of the tubercle bacillus from one point of the body to others is by way of the blood-vessels. For some time it was supposed that the acute miliary tuberculosis that so frequently supervenes on the more chronic processes, was something essentially different from the larger primary lesions; but the identity of the two sets of lesions had been accepted even before Koch had pointed out that the exciting cause of the two processes was the same. It was difficult to determine, however, how the tubercle bacillus made its way from the primary lesion to every organ and tissue of the body. Weigert was able to point out that in a case where there was tuberculosis of the wall of the thoracic duct the bacilli were carried from this lesion to the veins, from which they passed through the heart and thence were distributed to the capillaries of every part of the body. In these capillaries, blocking them and becoming attached to the endothelial lining, they again set up a proliferation in and around the capillary vessel, as a result of which the minute tubercles met with in this condition soon became manifest to the eye.

It must be remembered that these different methods of spread of the virus seldom occur alone. Whenever the air passages are affected we find, invariably, that the tubercle bacilli make their way into the surrounding lymph spaces, there giving rise to the proliferative and regenerative changes already described. Similarly, we find that in acute miliary tuberculosis there is, in each nodule, evidence of the invasion of the lymphatics by the tubercle bacillus, and it is because we have this affection of the lymphatics that the various lesions ultimately become localized. It is only through them that we can have a stimulation and proliferation of the connective tissue cells, new formation of fibrous tissue, and localization and absorption of the diseased tissues. I mention these methods of spread of the disease because in the various kinds of tuberculosis met with by the clinician, we have ample evidence that one or other predominates at different stages of the disease.

It may be well here to indicate, briefly, the history of a case of pulmonary tuberculosis, especially as by referring to this history in its various phases we may be able to gather how it is that, at one stage the disease may be perfectly curable, but how it is that, as the disease advances, the chances of permanent or even partial cure are more or less rapidly diminished. I wish you to pay special attention to the periods at which the various processes come on; and also the times during which they are prolonged; otherwise it may be difficult to understand why a patient who has had phthisis for perhaps two or three years and appears to have lost very little ground indeed, should suddenly begin to go down hill rapidly and die within a few months.

It has already been mentioned that in a case of phthisis apical catarrh is the first condition noticed, this being accompanied by congestion and followed by some consolidation the result of proliferation of the epithelial cells, such cells gradually accumulating and coming to fill the air vesicle. This breeding-ground for the tubercle bacillus may gradually spread in area; but it will be found that the bacilli causing degeneration of the epithelium make their way into the surrounding lymph spaces, there, especially if the tissues are well nourished, giving rise to the formation of fibrous tissue.

If at this stage the patient be placed under favorable conditions, of nutriment, of rest, so that the waste products of the body may be carried away regularly and systematically, the reaction of the tissues is so complete that the dead patch is practically surrounded and cut off; the bacilli remain inactive in the dead mass; or they may even be killed. The degenerated tissue is absorbed very gradually and there may be complete "cure," especially when the initial lesion has not reached any very great size. The loss of respiratory surface is so slight and the reserve so great that the patient may be considered to be practically normal again.

If, however, the patient be not placed under favorable conditions, or if after a short period of treatment he returns to his old life and habits, this focus of dead material may ultimately break through the surrounding layer of limiting tissue and a further considerable patch of tuberculous consolidation may be the result.

In most cases, especially if there be intermittent congestion of the surrounding tissues, the degenerated or caseous material may become softened, and it is during this stage of softening that secondary infection goes on most readily.

Let us suppose that this mass cut off from the bronchus with which the air vesicles were orig-

inally associated, extends to the wall, perhaps of another bronchus; as it advances in this wall it cuts off the vascular supply, first that of the peribronchial tissue and then that of the submucous tissue, until at last by destroying the vitality of the bronchial wall it brings about a process of ulceration; then the tuberculous material with its contained bacillus may immediately be carried into the air passages, whence it may be expectorated almost entirely, though in most cases a certain proportion of the softened material along with the bacilli is carried to other areas, where fresh tuberculous catarrhal pneumonia is induced, and the whole process may be repeated but upon a more extensive scale. This process may be again repeated—at each repetition, larger and larger areas being affected. It is evident that in such cases as those just described, the loss of lung tissue may be very great indeed, whether it be broken down or not—*i.e.*, whether the lung be merely consolidated or whether it be excavated. Even the great reserve mentioned above is unequal to the draft made on it, and even should the patient be patched up for a time he must face the fact that he is not cured and never can be, though under proper treatment and with great care he may continue to lead a useful if not very active life.

It is sometimes difficult to understand why the small hemorrhages so characteristic of the early stage of phthisis should occur so frequently especially when we remember that in the tuberculous areas themselves the blood-vessels are practically obliterated. It must be remembered, however, that around each tuberculous area the conditions of the vascular circulation are somewhat altered, owing to the fact that some of the vessels are closed; as a result of all this a collateral circulation must be set up and maintained. Moreover, an increased quantity of blood is required to meet the wants of the proliferating tissues; but we find that the hemorrhages usually take place as the result of some extra temporary strain and are an indication of local changes. It will be noted that in some of the specimens I show that we have a systematic invasion of the lung commencing at the apex and gradually working toward the base. It will be noted, moreover, that the basal processes are always more extensive, that the consolidation is more diffuse, and the degeneration more rapid than at the apex; that we have in fact a more markedly caseating catarrhal type in this position than at the apex. The whole of the lower lobe of the lung may be invaded in a few weeks, especially when the resisting powers of the tissues have been gradually broken down by overwork, general ill health, want of sufficient nutriment, imperfect oxidation of the blood and accumulation of waste products in the tissues.

These factors do not act at once; but at work over considerable periods they gradually wear down the resistance of the tissues, with the result that the tubercle bacillus finds an easy prey wherever it finds lodgment.

In addition to the catarrhal process, there is in most of these rapid cases of basal phthisis a more acute pneumonic condition, the air vesicles in the spaces between the catarrhal pneumonic patches in such cases being filled with a fibrinous exudate. The process seems to be associated with the alterations in the circulation, but partly to be the result of a secondary infection; wherever it occurs, however, it is a serious factor in the production of consolidation, and always accelerates the rapidity of the process, patients so affected, as a rule, dying quickly.

It will be seen at once from this rough description that a physician has a considerable period during which he may hope to treat his patient successfully, but that at any moment, almost, a series of more acute changes may supervene after which he has no right to expect recovery; though it must be acknowledged that in a few cases patients do recover even after such expectation is no longer justifiable. Nature is always more powerful than we give her credit for, and often helps us when we have given up all hope. This, however, is something we should never presume on, and the importance of the early diagnosis of tuberculosis can scarcely be too keenly appreciated, nor that of early treatment.

We now come to a phase of the question that has been recognized by many physicians but one that is not so generally recognized by the patient. A patient who has once suffered from tuberculosis must remember that although he may be partially protected (though of that, however, we as yet know nothing), he does not enjoy any definite immunity against future attacks of the disease; and it is absurd for any one to decry a system of treatment because it does not confer a lifelong immunity to the disease against which it is directed. I show you a specimen in which there is an old scar in the lung, from which all tuberculous material had disappeared, leaving a little nodule of pigmented fibrous tissue surrounding a few particles of calcareous matter. That patient suffered from phthisis many years ago and had recovered; but you will see that throughout the remainder of the lung we have now the lesions of an acute miliary tuberculosis; the patient succumbed to an infection in all probability of entirely new origin; though it is possible that it may have been the outcome of some old but latent lesion either in the lung or in some other part of the body, from which tuberculous virus has made its way into the blood-vessels and thence has been distributed throughout the body.

Such a case as this to my mind, though exceedingly encouraging in many ways, should lead us to insist that patients even after discharge from sanatoria where the treatment has been successful, should continue the treatment, perhaps in a modified form, throughout their whole life; as it is impossible to state when a patient can come back to the old conditions of life with impunity; in fact, one may lay it down as a general proposition that it is only as we insist on the improvement of the conditions of life wherever such im-

provement is possible, that we shall be able to diminish the morbidity as apart from the mortality, of tuberculosis. It is here that the medical officers of health, and sanitary officers can play so large a part; and that an institution of this kind can do so much to spread a knowledge of the importance of light and air in the home and in the workshop, of sufficient food even though plain, of the danger of prolonged periods of overwork, except in the case of the very strongest; and of the importance of periods of rest during which the organs and tissues of the body must not only be built up, but may get rid of the waste material that accumulates so rapidly during periods of active exertion.

This brings us to a very important question indeed. Although I have every faith in sending patients who can afford it to places where they can comfortably remain in the open air and where there is plenty of light, I think there is a danger, and a very great danger, of overlooking the fact that the open-air treatment may be carried out at the patient's home, and that so far as this branch of the treatment is concerned it is not so much a matter of getting a good climate as of getting pure, fresh air for the patient.

There can be no doubt that the sanatorium treatment has been successful, not because of any special climatic conditions associated with each institution, but because whatever the climate the patient has been encouraged to live practically in the open: diet, exercise, and rest, of course, being carefully attended to. All acknowledge that a sanatorium treatment is of inestimable value in tiding over the difficult and dangerous early period of the disease; but it will be still more valuable just in so far as it teaches the patient to carry out in his own home the principles and methods adopted in the sanatorium. It always seems to me that a patient will be much more likely to have faith in the efficacy of the methods used, if they are carried on in familiar surroundings and under conditions of climate, etc., to which he is usually exposed. If he is sent to a special climate resort, he is apt to think that the success of his treatment depends on something special in the climate; and while this is of course the case to some extent, in so far that in a bright, dry, bracing climate the open-air treatment is more agreeable and a cure effected somewhat more quickly perhaps, there is no fundamental differences between the two, the closer you can bring your patient to his every-day manner of life during treatment the more likely he will be to carry out your instructions after discharge from the sanatorium.

I may say that at Cambridge, a place little above the sea-level, situated in the fen district where fogs are frequent and sometimes very dense, great success has been attained in the open-air treatment of phthisical patients in the Addenbrookes Hospital. I mention this fact for what it is worth; but I think that it bears out the contention of some that the method of treatment is in most cases more important than the exact place in which it is carried on.

Ladies and gentlemen, those who are responsible for the inception, organization and working of this Institution, have undertaken what most of us consider to be one of the most beneficent works on which men can engage. The endowment is munificent; and as the workers are both capable and enthusiastic, I think that we may look forward with very bright hope to the outcome of the work carried on. But the work to be done cannot all be accomplished even under the favorable conditions that here obtain; and I would ask you not to be disappointed should you not attain all that you hope in the immediate future. There is much quiet and steady spade work to be done. You will, I know, relieve and cure many patients; but you have then touched but the fringe of a great problem. You have to determine the exact pathological conditions met with in individual patients and in groups; you have still much to learn concerning the condition of nutrition, of waste, and of repair; you have physical problems, chemical problems, bacteriological problems and others of the greatest complexity; these can be undertaken only by men skilled in methods and trained in accurate observation. They may have to work for years before they are able to gain results that can be utilized, or that can be brought into a great scheme of knowledge, from which further advances can be made; but we may all entertain the hope, and one well-founded, that under honest, persevering, patient investigation even the most difficult problems may be compelled to give up their solution. While working for the benefit of the individual, we must keep our mental vision fixed on a point beyond; on the possibility of preventing the invasion of the tissues by the tubercle bacillus; of studying the life-history of this organism so that in time as we gain the knowledge of the conditions under which it exists, both outside and in the body, we may gradually so circumscribe its sphere of operations that it may no longer remain a factor of disease especially when we are wise enough to insist on those improved sanitary and social conditions without whose aid the tubercle bacillus even to-day would lose much of the terror attached to its name. I congratulate the Henry Phipps Institute on what it has already achieved; but I hope for it and those associated with it a still more useful, beneficent and brilliant future.

Cryoscopy of Animal Organs. Just as normal blood and urine freezes at a certain temperature, definite figures can be obtained for entire organs, but the normal fluctuations are somewhat greater. The experiments of Blanck (Virchow's Archiv, Vol. 174, No. 2) were conducted chiefly with animal kidneys. The freezing point lies between $-0.86°$ C. and $-1.35°$ C., and is generally the same on both sides. By passing large quantities of water through the kidneys only slight changes occur, but alkaline waters have more effect. Diuretics such as diuretin and agurin reduce the osmotic tension of the kidney considerably. Phloridzin is without action; likewise chromate of potash and urinary stasis change the freezing point but little.

MEDICAL PROGRESS.

MEDICINE.

Some Points in Diagnosis of Smallpox.—The recent outbreak of smallpox in New York City has furnished considerable material for valuable conclusions in regard to the diagnosis of this disease. W. L. SOMERSET (N. Y. Med. Jour., Nov. 21, 1903), furnishes some very helpful hints in regard to the differential diagnosis of the milder cases, which are, as a rule, the ones which give rise to the greatest difficulties in diagnosis. Varicella is the disease which causes, perhaps, the most confusion, for there are some cases of this affection which closely simulate variola. Varicella can vary from an eruption most abundant to a few scattered vesicles or pustules. In many cases it invades the palms and soles of the feet and may attack the mucous membranes. The patient may also be very sick with considerable temperature. If, however, in variola the lesions are abundant they will be most so on the face—in varicella, on the trunk. Variola does not produce vesicles in twenty-four hours. Varicella is seldom seen before vesicles appear, and if so the diagnosis cannot be made. Varicella vesicles are translucent, the epidermis covering being very thin. They are never umbilicated, but when beginning to dry down they may be covered by apex crusts which require close inspection to be distinguished from umbilications. Varicella has no papular stage. The elevation of a chickenpox lesion is due, from the start, to the pushing up of the outer epidermis layer by serum, and this occurs within the first twenty-four hours. Concerning lesions succeeding each other in point of time, so that early and late appear side by side, it can only be said to be usual in one and exceptional in the other. In general, when the decision rests between these two diseases, if it is variola, the pathognomonic lesions will be found upon the face and extremities; if varicella, on the trunk. A face invaded by variola, confluent in the macular stage, may resemble measles, but there is no photophobia, no lacrymal flow, the invasion is shorter and the symptoms remit as the eruption appears. A careful examination of the history, the individual lesions and their site ought to differentiate all cases of variola from the pustular syphilide. Smallpox of to-day has not acquired any new capabilities, but it simply fails more and more to live up to its former standard. It may all be accounted for by diminished virulence of the contagium or diminished susceptibility of the patient.

Pulmonary and Cardiac Disturbances Accompanying Diseases of the Biliary Passages.—There have been observed many cases of biliary colic in which the cardinal symptoms of the affection such as pain on the right side and the like have been absent; the attacks being accompanied by cardiac or pulmonary phenomena, such as asthma, disturbance of the pulse rate and others. In some cases there even appeared an insufficiency of one of the cardiac valves, which, however, disappeared with the cessation of the attack. K. P. ROUSSK (Prakt. Vrach, Oct. 18 and 25, 1903), reports three cases of biliary calculi in which these reflex cardiopulmonary disturbances were quite marked during the attacks of colic. Thus one of them suffered from very severe dyspnea, during which there was a high degree of oxygen hunger. It is of interest to note that physical examination during one of these attacks of dyspnea failed to detect any difficulty in the ingress of air to the lungs. The heart showed an enlargement principally of the right ventricle, accentuation on the second pulmonary sound, and insufficiency of the mitral valve. As regards the pathogenesis of these disturbances the author considers them under three heads: Mechanical, poisonous (intoxication), and reflex. Of these he regards the last as of the greatest importance. It is considered that the mucous membrane of the biliary ducts serves as the starting point of the reflex act. The muscles of the biliary ducts and sphincter at the junction of the ductus choledochus and the duodenum are innervated by the vagus and sympathicus. This was proven experimentally, as well as during a laparotomy, when the operator by manipulating the region about the ductus choledochus caused repeatedly cessation of the right pulse, which reappeared as soon as the manipulations were stopped. The sympathetic is thought to be the path through which the reflex travels. In the absence of any causative agencies in the lungs and heart in certain cases of dyspnea the author advises to remember the possibility of cholelithiasis as the underlying cause of the condition.

Cysts of the Pancreas.—In an extensive paper, P. LAZARUS (Zeitsch. f. klin. Med., Vol. 51, Nos. 1 and 2) distinguishes five common varieties of pancreatic cysts. The gastrohepatic form, where the cysts develop between liver and lesser curvature, is rare. The dulness will here merge into the hepatic or cardiac dulness and with continued growth the cysts will fill up the lesser mental cavity and even extend through the foramen of Winslow. Trauma is the usual cause here, since the portion from which these cysts originate, the upper and anterior parts of the body, are exposed to injury more than other parts. The development in so unusual a direction is best explained by pathological and physiological adhesions, with the stomach, which prevent a downward extension. Sometimes the position is distinctly subphrenic, when adhesions to the diaphragm and vena cava are common. The retroventricular variety is still less frequent and especially unsuited for operation. Perigastritis and peripancreatitis generally present upward or downward growth. The typical pancreatic cyst is the gastrocolic species, since the natural tendency for all growths from the pancreas is into the omental bursa. The stomach will cover the upper and the colon the lower segment. In a fourth form the cyst extends into the transverse mesocolon and depending upon the position of the transverse colon, three subvarieties may be distinguished: the intermediary, superior and inferior. Lastly a prevertebral type is recognized, where the growth is downward in front of the vertebral column and kidneys. The most infrequent starting-point of cysts is the head, since the secretion can generally find an exit through the accessory duct if the main duct is blocked. Compression of the duodenum is common here and a sudden increase in volume through hemorrhage may lead to jaundice and acute intestinal obstruction. Edema of the lower extremities, owing to venous obstruction, has been noticed, and ascites from portal thrombosis may develop. Occasionally the right kidney is displaced and compressed, and rupture into the intestines may take place. Cysts of the body readily press on the stomach, colon and celiac plexus. Cysts of the tail are most common, are usually movable, and may have a pedicle so that they sink into the lower abdomen. Cysts with epithelial lining may be definite neoplasms, and here the cystoma glandulare proliferum is the best studied type. They may also result from retention secondary to interstitial pancreatitis, or from degeneration after postinfectious acute pancreatitis. False cysts, on the other hand, have as their most common cause softening, autodigestion after trauma and discharge of secretion and blood into the omentum after rupture. The remaining pancreatic tissue is often altered considerably; even in experimental cysts the surrounding tissue is much changed by interstitial inflammation or necrosis. The

contents of the cysts are said to be characteristic in that they contain pancreatic fluid, but all three ferments are detected but rarely. The diastatic ferment is most common, the tryptic least, since it is used up in digesting blood and tissue-shreds. Even if it occurs in the fluid withdrawn from an obscure cyst, this does not prove the pancreatic origin of the latter, since fluid from ovarian cysts may occasionally digest fibrin. Traumatic cysts need not always contain blood, since complete digestion and absorption often occurs in several weeks. Other common ingredients are serum-albumin (up to 2 per cent.), serum-globulin, mucin, pepton, and, more rarely, cholestrin, leucin, tyrosin and sugar. The sediment consists of epithelium, fattily degenerated round cells, fat crystals, leucocytes, altered red cells, pigment, mucin and salts. With exception of a few congenital cases, the most common etiological factors are trauma and chronic indurative changes, secondary to gastroduodenal catarrh, cholelithiasis, arteriosclerosis, alcoholism and syphilis; the acute infectious diseases and pregnancy play a less important part. The development is occasionally latent until the neighboring organs are pressed upon and the functions of the pancreas itself suffer, but often the symptoms of the primary disease precede. Where diabetes is present, digestion is seriously interfered with, so that the stools are rich in fat and undigested muscle-fibers, but such stools are by no means pathognomonic, since fat may be absent in advanced cases and muscle-fibers may also occur in normal feces. The earliest and most constant symptom is pain; it may persist for years before the real condition is suspected, and is generally localized where the tumor develops. Occasionally the pains resemble gastric crises and they are especially severe where stones are present. Other important signs are intermittent increase and disappearance of the tumor and emaciation, while salivation was not observed. The most marked pressure symptoms occur with cysts of the head; they are responsible for the large number of gastric and intestinal complaints, which are invariably present. Rare complications are compression of the choledochus, with icterus and colic; of the portal vein with ascites; of the abdominal aorta with pathological murmurs and pulsation and of the splenic vessels with splenic enlargement. Traumatic cysts are generally ushered in by signs of shock, hemorrhage and injury of other abdominal organs, especially the stomach, and they may be accompanied by large omental hematomata, which generally heal rapidly after they are evacuated. The processes of cyst-formation and induration may here require many years. A rare complication is displacement of the ureter; a most dangerous one, suppuration and rupture of the cyst. Suppurative peritonitis is not due to discharge of pancreatic fluid into the peritoneum, since this is aseptic, but invariably to bacterial infection from the blood or gastro-intestinal tract.

SURGERY.

Functional Renal Diagnosis.—Concerning cryoscopic renal diagnosis, the opinions are still very much divided and enthusiastic reports alternate with more conservative articles. The paper of A. Göbell (Münch. med. Woch., Nov. 17, 1903) belongs to the latter class, for its author had some experiences which make him doubt that absolute reliance in the method is safe. The character of the food and the amount of fluid ingested seem to have a marked influence upon the freezing-point, but even if the diet is simple and absolutely uniform the figures vary within very wide limits. Several cases are reported where the wrong kidney would have been extirpated, if the molecular concentration alone had been taken into consideration. Much more satisfactory results are obtained if attention is also paid to the daily amount of urine and if renal activity is expressed in so many daily molecules. In all cases the diet should be controlled and the catheters should be introduced a definite period after a meal and left in position for at least two to three hours, since fluctuations are very common. At best the method is only approximate, but, though troublesome, it offers valuable aid in conjunction with other data.

Improvements in Narcosis.—A series of articles on narcosis is contained in the Münch. med. Woch., Nov. 17, 1903, which give a good account of the modern tendencies in this important specialty. H. Fuchs says ether is again taking the place of chloroform, since it was shown that the ideal ether narcosis is one not accompanied by suffocation and not necessitating the use of a large amount of the drug. The best method at present is the following: The patient first receives a dose of morphine half an hour before the operation. In case of laparotomies it is best to substitute codeine (1 to 2½ grains), since this is less liable to interfere with peristalsis after the operation. The patient is then etherized, drop by drop, with an ordinary chloroform mask. The musculature is generally relaxed in ten to twenty minutes after the use of one to two ounces of ether. Sometimes it is desirable to hasten the first stage by giving a few drops of chloroform after the ether has sufficiently stimulated the heart. The best position for the head is that of overextension by means of a pillow under the shoulders. The after-effects are exceptionally mild, and collapse during operation is almost impossible. C. Hofmann also looks upon the drop-method of etherizing as the narcosis of the future; he believes it approaches the ideal in every way. C. Hartog has a few words to say in favor of the morphine-scopolamine method which he considers free from danger if used properly, and if followed by ether-narcosis. Half a milligram of scopolamine ($^1/_{120}$ grain), and one centigram ($^1/_6$ grain) of morphine are injected ½ to 1 hour before operation, when the patients will invariably go to sleep with a minimum amount of ether and will exhibit none of the usual disagreeable symptoms. B. Korff employs twice the amount of scopolamine and ⅓ grain of morphine distributed over three doses given 2½, 1½, and ½ hours before the operation, and generally dispenses with other anesthetics. Pulse and respiration are affected only slightly, salivation is moderate, and the intestines and urine are not affected, since the bad effects of each drug are paralyzed by the other. Supervision is hardly necessary, though sometimes the tongue must be pulled forward. The stomach need not be entirely empty before operation and small amounts of water may be given soon after, as they do not provoke vomiting.

Traumatic Aneurism of the Subclavian, Produced by Fracture of the Clavicle.—Aneurism of the subclavian artery is rare among surgical lesions. When the condition has been brought about by fracture of the clavicle, its rarity is so great as to make the condition almost anomalous. William Taylor (Annals of Surgery, Nov., 1903), reports a case of this complication. It is remarkable that injury to the bone so frequently leads to arterial or venous rupture, and likewise remarkable, in view of the proximity of the apices of the lungs and the cords of the brachial plexus, that these two should be comparatively immune from injury. In the Lancet of July 6, 1850, Sir Robert Peel is reported to have died from an injury to the subclavian vein, due to fractured clavicle. As in probably all cases, there was here a comminuted fracture of the clavicle. The English and French lit-

erature contains only 10 or 20 cases of injury to the nerves and 5 cases of injury to the artery. There are many others recorded which terminated fatally, but which were associated with crushing injuries, or were lesions produced by bullets or other penetrating missiles. In these cases the complications have been attributed rather to the passage of the bullet or sabre, as the case might be, than to the fragments of the broken bone. Furthermore, it is probable that in the majority of these cases not alone is the clavicle broken, but the first and second ribs as well. The bone spicules, if such existed, having arisen from the ribs, rather than from the clavicle. The case reported by Taylor was one of the few which has been cured by operation. It was decided to place a temporary ligature on the first portion of the subclavian. An incision was therefore made around the inner end of the clavicle and the bone was divided two inches from its end and the part resected. The encroachment of the tumor on the small space occupied by this portion of the vessel gave rise to insurmountable difficulties. Recourse was had to an opening of the sac and attempt to secure the injured vessel. Accordingly the middle third of the clavicle was removed, so that digital pressure might be applied directly. The tumor was incised and the clots turned out. It was impossible to pass an aneurism needle, therefore forceps were applied to the opening in the artery. The convalescence was uneventful, the forceps having been removed on the twelfth day. The patient has not yet entirely recovered the use of his arm, but power is gradually returning.

New Method of Intestinal Union.—Two important points in the problem of intestinal union are still unsettled. The first is the question of the penetration of all coats of the intestines, and second the use of a continuous or an interrupted suture. J. SHELTON HORSLEY (Annals of Surgery, Nov., 1903) details the steps of his operation as follows: Intestinal clamps are placed, the mesentery is incised, and if need be, resected. The forceps that clamp the vessels are also made to include both layers of peritoneum as they separate from the mesentery to encircle the bowels. The tissue within the bite of the forceps is ligated with fine silk so covering the bowel, which is usually devoid of peritoneum. The bowel is then divided and the convex borders placed in contact and held there with forceps. Both walls of the intestines are now transfixed with No. 2 braided silk, about half-way between the mesenteric insertion and the forceps. This is tied. Part of the intestinal walls forming a crescentic area, the center of which is held by the forceps, is now cut out, and the cut edges sutured through and through. The needle is then thrust directly through the intestinal wall close to the right of its last puncture and emerges from the serosa. The character of the stitch is now changed to a Cushing right angle continuous suture, penetrating all coats and inverting the margins. Firm traction is maintained on the thread. When the first knot is reached it is invaginated and the suture continued by two more insertions of the needle. After this suturing is completed, scarcely any of the thread can be seen. The mesentery is then sewed up with a continuous suture. Nineteen dogs were operated upon by this method without a death. Evans has demonstrated that the danger from stricture following intestinal resection is overrated. Owing to the excision of the crescentic area, the diameter of the intestine at the point of union is greater than its normal size. The author believes the continuous suture is by all odds preferable to the interrupted. The operation can be done in eight minutes. The results of hydrostatic pressure on the unions obtained by this stitch, show that a suture through all coats is stronger during the first six days than one including the submucosa only. The Connell method stands more pressure at the end of the first and the sixth day, the new method stands as much as the Connell during the critical time of intestinal union, which is the third and fourth days.

Dislocation of the Ulnar Nerve.—Only 15 cases of this lesion had been reported, and until the present paper, no summary had been made. FARRAR COBB (Annals of Surgery, Nov., 1903) analyzes these and adds a case of his own. His conclusions are first, that the operation for this rare but disabling lesion give every chance of cure. Second, it is only in the most severe cases of dislocation that operation should be undertaken, and then only for the symptoms caused by the dislocation rather than for the lesion itself. Third, the steps of the operation are as follows: A curved incision 3½ inches long, midway between the olecranon and the tip of the internal condyle. The fibers of the triceps muscle should now be dissected up and removed from the groove previously and normally occupied by the nerve. The nerve is now placed in its groove, and the fibers, together with the portion of the fascia and the triceps are carefully sutured to the fascia of the flexo-carpi-ulnaris. The arm is put up in extension on a straight internal splint. There should be no pain after the operation. At the end of two weeks, the straight splint should be substituted for a right angle splint for one week. Active motion of the arm may be allowed after four weeks.

GENITO-URINARY AND SKIN DISEASES.

Multiple Zona.—Cases of symmetrical bilateral "herpes zoster" are extremely rare, but there are certainly many in which the eruption appears in the distribution of more than one nerve. Of 231 cases of zona seen by P. FABRE (Le Progrès Médical, Oct. 24, 1903) not one was symmetrical and only one bilateral, this involving a right intercostal space, and the back of the left thigh along the sciatica. There were duplicate unilateral zonas in four cases, one affecting the second, third and fourth intercostal spaces and the arm, the other three the lumbo-inguinal region and the corresponding thigh. Of bifurcated zonas there were seventeen, and four in which there was a true trifurcation. Zona, is, therefore, not always a single line or band, nor is it an eruption always limited to the course or distribution of a single nerve.

Choice of Operation for Hypertrophied Prostate.—Operations upon the prostate gland are no longer looked upon with so much dread as formerly and there is little doubt but what they will soon be considered within the province of most of our able surgeons. W. MEYER (Med. Rec., Oct. 24, 1903) gives his experiences with the various operations upon the prostate during the past five or six years, and now believes that those operations making a direct attack upon the enlarged gland are preferable to those aiming to exert an indirect influence. Operations upon the testicles and vas deferens should be done only as a very last resort and only after a direct attack has first been made. There are two useful procedures for the direct treatment, viz., prostatectomy and galvanocaustic prostatotomy (Bottini's operation). If the gland can be removed by operating from below, this procedure deserves the preference, were it for the sole reason that the wound which is made for shelling out the gland can be at the same time used for drainage. Besides this, perineal prostatectomy has the advantage of permitting operation under the operator's eyes. In selecting the method indicated in the given case we must individualize and be guided by anatomic,

pathologic and social conditions. He almost invariably recommends the cutting operation in patients with a large hard gland, also in patients with a gland of medium consistency if they seem strong enough to stand the operation and general anesthesia. He further advises protatectomy when the median lobe is present or in patients who are desirous of being relieved of their trouble at one sitting at all hazards. If the gland is soft and compressible, particularly if not palpable by rectum (the cystoscope haveing determined the diagnosis); if the patient is old and run down, he advises the Bottini operation, making the family fully aware of what may be expected. This does not preclude the possibility of a subsequent prostatectomy if necessary, and usually in itself secures good results at much less risk to the patient's life. Surgeons should, therefore, familiarize themselves with both operations in order to be in a position to do justice to their patients, and to insure that debilitated men who seem unfit subjects for the more radical operation may not be at once relegated to catheter life.

Urticaria Medicamentosa.—A hitherto unnoticed sequeln from the use of suprarenal extract is reported by A. ROSENBERG (Berl. klin. Woch., Oct. 12, 1903). The patient, a young woman in good physical condition, presented what appeared to be symptoms of an accessory nasal sinusitis. A small swab saturated with suprarenal extract was applied to the swollen inferior turbinate. It brought on an unpleasant disturbance of smell and within a few hours was followed by a diffuse urticaria extending over the trunk and arms. This disappeared after a short time, but about a week later, when the treatment was repeated, the same trouble reappeared. Swabs saturated with water or cocaine failed to produce the same effect. The author believes that this urticaria was caused either by the absorption of the drug or was a reflex disturbance brought about by an irritation of the olfactory nerve, the patient complaining of an unpleasant sensation of smell at the time when the suprarenal extract was applied.

Operative Cure of Sterility from Obstruction at the Epididymis.—Experimental work upon dogs has shown that when the vas was cut a short distance from its origin in the epididymis and an anastomosis of this divided end with the heads of the epididymis was made subsequent ejaculations were found to contain apparently normal spermatozooids. E. MARTIN (N. Y. Med. Jour., Oct. 10, 1903) has learned by morphological study of the human spermatozooid taken from the rete testis, the upper part of the epididymis and the vas that these spermatozooids seemed to undergo a developmental change in their progress through the organ, and he was therefore a little doubtful concerning the ultimate success of such a transplanting operation in man. An opportunity for testing the result of such an operation was given him by a man who had been married for several years and to whom no children had been born. The wife had been subjected to dilatation and curettement before it was discovered that her husband was sterile. He had suffered from two severe attacks of gonorrhea, one accompanied with bilateral epididymitis. Repeated examination of the seminal fluid resulted in the finding of only two or three poorly formed spermatozooids on one or two occasions. Operation was decided upon, and the vas of the left side was freed at about the level of the top of the testis, and, by means of a sharp-pointed pair of scissors, a slender bistoury, and a grooved director, its lumen was opened by a longitudinal cut a quarter of an inch long. A portion of the head of the epididymis was then picked up and excised. A few minute whitish drops at once appeared on the cut surface, made up mostly of spermatozooids. Into the wound of the epididymis the vas was implanted by means of fine silver wire and the skin closed by catgut. Examination of the spermatic fluid subsequently showed a goodly number of spermatozooids, and 281 days after resuming marital relations his wife was delivered of a normal girl baby.

Value of Albuminuria in Differentiating Pyelitis from Cystitis.—There are many cases of pyelitis in which the local symptoms are so indefinite that a diagnosis becomes very difficult. Even a careful microscopical examination may disclose nothing characteristic, for it is well known that no great reliance can be placed upon the so-called epithelial cells of the pelvis. Cystoscopy, ureteral catheterization and the freezing point of the urine are all very helpful means of diagnosis in the hands of the trained, but these means are by no means accessible to the ordinary physician. T. R. BROWN (N. Y. Med. Jour., Oct. 17, 1903) has found that the amount of albuminuria is of great help in differentiating a cystitis from pyelitis. Pyemia due to a cystitis, even if of high grade, is associated with but a small amount of albumin if the urine is examined soon after catherization, and if the pyemia is not accompanied by hematuria. On the other hand, in all cases of pyelitis, even if the pyemia is slight, there is always, or at least almost always, a considerable quantity of albumin present. A microscopical examination will easily disclose the presence of red blood cells if they are in sufficient number to be of any importance in causing the albuminuria.

HISTOLOGY, PATHOLOGY AND BACTERIOLOGY.

Action of Purin Bodies.—The purin bodies normally excreted in the urine (guanin, hypoxanthin, uric acid) were injected in medium doses into rabbits by J. W. HALL (Virchow's Archiv, Vol. 174, No. 2) in order to study their effect upon the organism. Considerable loss of weight followed, the blood-pressure and size of the heart were not affected and in the blood the lymphocytes, multinuclear leucocytes and basophile cells were augmented in number. A histological examination of the heart, large arteries, lung and nerve-cells gave no change; the kidneys showed slight hyperemia, slight thickening of the intima of the smaller arterioles and beginning degeneration of the secreting epithelium. In the bone-marrow very many lymphocytes and nucleated reds were found, and cellular degeneration and vacuolization occurred in the liver. It is possible that some of the changes of chronic interstitial nephritis in man are due to retained purin bodies.

Disintegration of Rabid Brain Substance.—Although no organism causally related to rabies has been demonstrated in the tissues of animals dying of this infection, according to J. O. W. BARRATT (Proc. of the Royal Soc., Oct. 31, 1903), yet it has long been supposed that the virus consists of an organism, since it is capable of indefinite increase when passed from animal to animal. This supposition is also strengthened by the following experiment performed by the author: The rabid brain substance of a rabbit was disintegrated at the temperature of liquid air for from half to one hour, and it was found that this abolished its virulence. It was now necessary to ascertain whether any substance was produced or set free during disintegration, which was in itself capable of destroying "virus fixe," since it is known that immunizing substances are formed by animals infected with, or immunized against, rabies. Intracerebral injection of a mixture of disintegrated and virulent brain substance, in a preparation of 5 to 1, practised upon rabbits, was followed by rabies, thus showing the absence of a rabicide substance in disintegrated rabid brain. MacFayden proved that exposure of rabid brain-substance to the temperature of liquid air for three months fails to deprive it of its virulence.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, JANUARY 2, 1904.

RESPONSIBILITY FOR TYPHOID FEVER.

THE year just closing has been remarkable for its epidemics of typhoid. Not only has the number been large, but there have been two outbreaks which must be regarded as the greatest explosions of typhoid fever which this country has seen. At Ithaca there were 1,300 cases, and at Butler, Pa., according to an exhaustive report by Dr. George A. Soper, published in the *Engineering News* of December 24, the number of cases to December 17 was 1,270, with a prospect of more.

That typhoid is increasing in sporadic and endemic, as well as epidemic, form, is a fact which is attested by the newspapers and the reports of health boards; and this in the face of the fact that there is no communicable disease whose channels of infection are more clearly understood and can be more securely guarded. That public interest in its prevention is sporadic and ephemeral is not only to be deprecated but it should be set down as a national crime.

Typhoid epidemics are usually due, in the first place, to neglect on the part of purveyors of water and milk, and incompetence on the part of boards of health. Proper sanitary surveillance in these directions is capable of affording complete protection against typhoid, but sufficient care is rarely exercised to keep public water and milk supplies free from the danger of infection. After reading the article on "The Management of Typhoid Fever Epidemics," which appears in this issue, it seems to be a matter of chance that epidemics are not more numerous than they are. The public should recognize that it is the business of the purveyors of water and milk to take the measures necessary for their protection and the business of boards of health to see that such measures are faithfully carried out. The growing frequency of typhoid epidemics indicates that legal action for criminal carelessness in failing to exercise due diligence is apparently needed to bring water works officials, dairymen and boards of health to a proper sense of their responsibilities.

In the second place, typhoid fever spreads to a needless extent in households, through the want of a knowledge of the preventive measures which should be adopted. Such precautions as are taken in families in which a case of fever occurs are usually those which can be gleaned from the hasty instructions of the physician, and too frequently consist of the perfunctory use of a certain patented brand of disinfectant. If physicians would stop to consider that many of these so-called disinfectants are not only adulterated and unscientific in character, but ineffective in action and far inferior to simple reagents which can easily be prepared at home, they would probably hesitate to give them an endorsement. Typhoid fever spreads in households chiefly because disinfection, which is both necessary and sufficient as a protection against the transmission of the disease, is usually a farce.

There is a distinct lesson in all this. It is clear that reforms are needed at the water works, dairy and sick room. Prevention must be practised and prevention must be taught. Public and domestic hygiene should be recognized as a factor in education. Our universities, colleges and medical schools, which now generally omit this subject from their curricula or teach it in a feeble and perfunctory way, should establish chairs and departments of hygiene. With a settled purpose to accomplish this, means can be found for securing the funds. It is said that philanthropists of enormous means are seeking opportunities for the investment of money where it will be useful in reducing the sum of human suffering and will advance the best interests of mankind. No better opportunity for such noble work could be offered to men of wealth than the founding of chairs of hygiene in our medical schools and universities.

AUTOMOBILING AND NERVOUS MANIFESTATIONS.

It is evident from recent reports in the medical press, especially in France, where the practice of automobiling is more common than in this country, that in the very near future physicians are to be called upon to treat a number of nervous symptoms traceable to the excitement and mental tension of rapid traveling with the emotional repression necessary to secure a reasonable feeling of enjoyment, while speeding rapidly with risks and dangers constantly at hand. The most distinctive symptom complex that has thus far been described is a neurosis of anxiety.

In a recent study containing some interesting observations on the neurosis of anxiety in the *Archives de Neurologie* (Vol. 15, 1903, No. 89), Dr. Hartenburg describes a typical case that may prove a helpful guide to those who are brought in professional contact with the affection for the first time. The automobilist patient in this case had no difficulties as long as he confined his riding to short trips not far from his home; when he attempted long journeys, however, symptoms developed. In spite of the great fatigue consequent upon the close, prolonged attention in guiding his machine the patient was able to continue his riding for three successive days, but on the fourth day he suffered from severe symptoms. There was pain in the epigastric region, and the general nervousness incident to extreme emotion. This was followed by a chill, with chattering of teeth, shivering accompanied by palpitation of the heart and an overwhelming fear of sudden death.

These symptoms cleared up under rest and ordinary care. A three days' journey some months later was apparently completed in good condition, for the patient had a good appetite and was so naturally fatigued as to get to sleep promptly. After a couple of hours of sleep, however, he was awakened with an extreme sense of terror. As before, the main element of this was an uncontrollable sense of impending death. The palpitation of the heart was so severe that he felt sure his heart would break and that he would instantly die. A careful examination of his heart by medical consultants made afterward showed that there was absolutely no heart lesion. All the consultants agree that his symptoms were due entirely to the nervous condition induced by the emotional strain of automobiling, while the crisis of the case was brought on by acute nervous indigestion. The patient was advised to give up automobiling, and since then has had no recurrence of these attacks.

It is not only, however, as a result of automobiling, but also as a cause of certain of the phenomena of injudicious speeding in automobiles that nervous symptoms are to be brought to the attention of the medical profession. In the discussion before the Society of Hypnology and Psychology, reported in the November number, 1903, of the *Journal of Nervous and Mental Disease*, a number of medical experts testified that many of the reckless drivers of automobiles are really individuals who are under the influence of a sort of speed intoxication, until there is practically complete loss of self-mastery. Dr. Hachet-Souplet explains that the intense impressions which are borne in on a man by the consciousness of high speed entirely under his own control often carry him completely away, so that the worse side of his nature gains the upper hand, and combativeness, spitefulness and violence take the place of his ordinary qualities. Berillon suggests that there is a great analogy between the euphoria—the pleasurable sensations of speed and those produced by morphine. The sense of levitation that follows morphine is likely to be felt, particularly when traveling at high speed in the open air, and there goes with it constantly a lack of control of will power. Paul Magnin considers that the indulgence in speed is not unlike indulgence in tobacco or alcohol. It is an individual affair, and, as is well known, many persons are unable to keep from abusing these indulgences. Some are affected so as to be deprived of all power of moderation, even to the extent of losing their instinct of self-preservation.

It appears then that the new occupation of the leisure class may prove a fruitful source of study for the physicians of the twentieth century. In the meantime it would be well if precautions were taken as regards the physical and mental health of those who are permitted to drive automobiles on crowded streets, especially when the machines are of the twenty to forty horse-power type. There is more than a suspicion that some recent accidents at night have been due to defects of vision, or color-blindness, which prevented the drivers from realizing the dangers of excavations and obstructions guarded by red lights. It is clear that permission to drive such heavy machines should not be accorded to anyone who has ever exhibited any signs of mental disequilibrium, since it is almost sure that the excitement and mental strain of automobilism tend to bring on

the manifestations of lack of control so that even healthy persons find it hard enough to retain their true mental balance.

As with regard to nearly every other important innovation in modern life there is a medical side to automobilism, a question involving danger of loss of life and limb that has been very calmly ignored. So far, in this country, we have had but few reports of the neuroses caused by and consequent upon automobiling at high speeds. It cannot be that American physicians have been without experience. It is more probable that their attention has not been seriously directed to the conditions but that now we shall hear more of them.

THE TYPHOID COST OF THE PHILIPPINES.

ALL of our experiences with wars and campaigning outside of our own territory have cost us dear in deaths from diseases brought home, and distributed by the returning soldiers. During the Spanish-American war the unfortunate conditions that developed in the camps even at home proved serious by giving opportunities for the wide distribution of typhoid germs.

It is probable that some of the malaria of recent years, in districts formerly little affected by its germ, has been due to the same cause. Relapses of malaria are not uncommon in the spring-time and so the mosquito gets the chance to become inoculated by the malarial parasites and to spread them in a region never before infected. The epidemic of smallpox which occurred in this country during the two years following the Spanish-American war was undoubtedly due to the importation of this disease by the campaigners from Cuba and Porto Rico and its transfer to many parts of the country by these discharged soldiers. This has already cost many thousands of lives and the end is not yet.

During the last three years there has been a noteworthy tendency to outbreaks of typhoid fever which did not exist for at least a decade before the Spanish-American War. From a large number of the smaller towns throughout the country have come reports of the existence of typhoid fever in epidemic form. At least four university towns have been badly frightened by the presence of typhoid and one of them suffered severely from the ravages of the disease. There is a general feeling of insecurity with regard to typhoid that probably portends the occurrence of further epidemics in the near future. We now know that typhoid fever is not the result of unsanitary conditions in general, or even of the contamination of drinking water by sewage, or by excrementitious material from human beings unless those human beings have been suffering from typhoid fever. Unless the principle that typhoid fever never originates *de novo* is true, that is, unless there is an absolute connection of any given case with a preceding one of the disease, all our modern bacteriology is founded on a false assumption.

It is evident that a large number of scattered foci of typhoid fever have somehow come into existence in this country and that it is from these that the specific germs succeed in finding their way into drinking water or into milk or other food materials to cause the disease in new subjects. The only possible cause for this renewed activity and widespread distribution must be some special opportunity for infection incurred by many individuals in different parts of the country. The ideal opportunity for this unfortunate process has evidently occurred in the Philippines. Typhoid fever has been commonly epidemic there and during the last two years, many hundreds of discharged soldiers have returned to their homes in the smaller towns throughout the United States, while, probably, still the hosts of typhoid bacilli. It is possible at times that the attack of the disease during their campaigning may have been so slight that in the tropical climate, with the liability to passing fevers among the unacclimated, the affection may have been unrecognized. Furthermore in abortive attacks of typhoid fever, we do not know how long the patient's stools may continue to contain typhoid fever germs. We know that the urine has been shown to be infectious from the presence of typhoid bacilli for many weeks and sometimes for months after convalescence from the disease has been fully established.

It is very evident that, to the calculated cost of our new possessions in treasure and in soldiers there must be added the fatal results of these epidemics at home. The only possible advantage to be derived from the present unfortunate situation is to see that the lessons of these epidemics shall not be lost. We are now made sure that the length of time during which a convalescent from typhoid fever may continue to be a source of infection for others is indeterminate. The fact that typhoid bacilli may remain absolutely latent in the bone-marrow for many years after an attack of typhoid fever and then after the immunity fol-

lowing the original attack has passed off again become a source of danger, shows that there is much yet to be learned in this matter.

Another and even more important lesson is that the government shall take special care that returning soldiers may not prove sources of infection. It would seem that soldiers should not be allowed to go directly from foreign countries to their homes, but that their transfer to this country should be made some months before their discharge in order to be sure that the possibilities for the conveyance and distribution of infection to others shall have disappeared before they return to civic life.

The recent experiences in this country have taught us that war still remains a serious source of disease. Before the Spanish-American war it was thought that the development of sanitary science had reached a point that would enable the army medical department to preserve soldiers from epidemic disease. The idea was a complete illusion. The medical history of this country since the war, shows the necessity for precautions after men have been assembled in large bodies in tropical and unsanitary climates and must eventually add another chapter to the science of military hygiene. Let us hope that the lessons thus afforded shall not be neglected on the assumption that these calamities are due to other causes and not to the perfectly corrigible elements in our present conditions as an expanding nation.

ECHOES AND NEWS.

NEW YORK.

Bacteriologist to the Orange Hospital.—Dr. Ellen L. Lowell, of New York, has been appointed chief bacteriologist at the Graves Pathological Laboratory of the Orange Memorial Hospital. She will have entire charge. Dr. Lowell is a graduate of Leland Stanford University, and received her degree of M.D. from Johns Hopkins University. She is a member of the noted Massachusetts Lowell family.

Physician Hurt in Runaway.—Dr. N. E. Landon, of Newark, N. Y., one of the best known physicians in Central New York, was seriously injured on Christmas day in a runaway accident. He was riding behind a team of young horses when they became frightened at the cars and ran away. The doctor was thrown out and severely cut and bruised about the head and face. Medical assistance was summoned from this city, and it is believed that he will recover, although he is in a very serious condition.

New York's Low Death Rate.—Dr. William H. Guilfoy, Registrar of Records of the Health Department reports that the percentage of deaths will probably be found to be 18.15 for each 1,000 of the population. The estimated total deaths from all causes in the greater city for the year was placed by Dr. Guilfoy at about 67,000. The percentage for the year 1902, the lowest recorded up to that time, was 18.75. The union of all the boroughs into the greater city, he said, tended to lower the average of the death rate, because the rate is always higher in Manhattan and the Bronx than in the outlying boroughs. Dr. Guilfoy admits that not all the credit of the low death rate is due to Commissioner Lederle's administration of the department, efficient as that had been, adding: "It is in a great measure the fortunate dispensation of the power which rules the weather, and which holds the prevalence of diseases in check. The last two summers were remarkably cool, for example, very much decreasing the death rate among infants."

Medical Examination in Squadron A.—The following questions were asked the candidates for promotion as medical officers of Squadron A, by the headquarters examining board at its recent session. The board consists of Colonel George R. Fowler, of General Roe's staff, the Surgeon-General of the State of New York, Major Henry P. de Forest, Surgeon of the Thirteenth Regiment, Heavy Artillery, and Lieutenant Albert F. Brugman, Surgeon of the Second Battery, Light Artillery:

Anatomy.—(1) Describe the surgical anatomy of the carotid artery. (2) Describe the shoulder joint. (3) Describe the motor area of the brain.

Surgery.—(1) Discuss the question of probing in gunshot wounds of the abdomen. (2) Describe the symptoms and surgical treatment of obstructive jaundice. (3) A soldier in action receives a fracture of the femur in its middle third. Describe an improvised splint to be used in the field, and then the best appliance to be used when he reaches the permanent hospital.

Materia Medica.—(1) Name the principal alkaloids of opium, belladonna and of nux vomica. Give dosage of each. (2) What is the dose and composition of salol? (3) Write a prescription for the mixed treatment of syphilis.

Practice.—(1) Describe somewhat in detail the treatment of uremic convulsions. (2) What cardiac symptoms arise from the overuse of tobacco? How would you treat these? (3) Mention the principal respiratory diseases to which soldiers in camp are subject. Describe in detail the symptoms, diagnosis and treatment of one of them.

Camp Sanitation.—(1) Describe the location, construction and care of latrines in an army camp. (2) Describe in detail the best method of caring for kitchens and garbage in camp. (3) What camp diseases are in great measure due to pollution of the water supply and what means of prophylaxis should be employed?

Dr. Russell Bellamy was the successful candidate and has just been commissioned Captain and Assistant Surgeon of Squadron A, N. G. N. Y. He has been a member of the squadron for eight years, and was a private in Troop 2 for three years.

Pneumonia Epidemic in New York.—Dr. Herman M. Biggs, medical officer of the Department of Health, is making a careful study of the steady growth of pneumonia in this city. One result has been the adding of the disease to the list of those which must be reported to the bureau of contagious diseases as communicable. The records of the department show considerable increase in the number of cases of pneumonia this year over last year. In the week ended Nov. 28, last year, there were 116 cases; this year in the corresponding week there were 164 cases. For the week ended Dec. 12 there were 172 cases, against 105 last year. For the week ended Dec. 19 there was an increase of 68 cases over

the corresponding week of last year. Pneumonia increased its number of victims to 272 during the week which closed Dec. 28. This is the record for any one week in the history of the greater city, as it exceeds by three the number of deaths recorded last week from the disease. During the corresponding week last year 216 deaths from pneumonia were recorded, and that was then regarded as an unusually large number.

"We look," said the Registrar of Records in the Health Department, "for a lessening of the number if the present weather conditions continue. The deaths this week are further confirmation of the theory that pneumonia is an infectious disease, as in the previous weeks the thickly populated and crowded sections show the greatest number of deaths. The public should be especially careful during the present epidemic to avoid colds and to use every possible means to preserve the general health."

PHILADELPHIA.

Entertainment of Dr. Woodhead.—During his stay in this city, Dr. G. Sims Woodhead, of England, who delivered the third in the series of lectures under the auspices of the Phipps Institute, was entertained by several of the prominent physicians. On Saturday evening Dr. Joseph McFarland gave a dinner in his honor at the Bellevue Hotel. On Monday Dr. W. M. L. Coplin entertained him at luncheon at the University Club and in the evening he was given a dinner at the Rittenhouse Club by Dr. J. H. Musser. A reception followed the lecture on Tuesday evening and on Wednesday Dr. Ravenel, whose guest the distinguished visitor has been, gave a reception in his honor.

New Test for Pharmacists.—A decided innovation will be made by the State Pharmaceutical Board at the next examination which will be held in this city January 16. In addition to the usual written examination those applying for pharmacist's certificate will also be obliged to pass a laboratory test. Those applying for the certificate of qualified assistant will be given only a written examination as heretofore. The entire board will attend as the examination will be held only in the one city instead of at Pittsburg also as has been the custom formerly.

Drug Trust to Raise Prices.—The Philadelphia Association of Retail Druggists will after January 1 put into operation its new price schedule for proprietary articles. During the past year efforts to obtain full prices for ten-cent goods have been so successful that efforts will be made to secure the same scale for 25 and 50-cent articles. Several of the largest dealers have refused to join the association and persist in selling goods at their own price. Attempts on the part of wholesalers to refuse to supply them with goods have been met with threats of resorting to legal redress and the trust has been obliged to proceed very cautiously.

Physicians Asked to Aid in Stamping Out Smallpox.—Director Martin has sent a copy of the following letter to each physician in the city: "The conditions in Philadelphia are such as to threaten a grave epidemic of smallpox. Can you help in the preventive work by urging upon your patients and all the members of their households immediate vaccination of all unvaccinated persons, of all children over 12 who have been vaccinated successfully in infancy, of all adults who have not been vaccinated successfully within the last five years?"

Pathological Society.—The annual exhibition meeting of the Philadelphia Pathological Society will be held on the evening of January 14 in the Mutter Museum of the College of Physicians. Gross and microscopic specimens of all departments of human and animal pathology will be on exhibition.

Railway Accidents During 1902.—During the year ended June 30, 1903, a total of 26,503 persons were killed or injured on the steam and street railways of Pennsylvania. Of the passengers carried on steam cars 98 were killed and 2,713 injured; among the employes 1,323 were killed and 14,059 injured; of other persons 2,298 were killed and 2,716 injured. These figures show, as compared with last year, a reduction in the number of injured of 3,292; an increase in deaths of 446. On the street railways the killed and injured were as follows: Passengers, 41 and 1,727; employes, 21 and 252; other persons, 165 and 1,090.

CHICAGO.

New Buildings for Dunning.—The County Board of Commissioners has decided to erect at Dunning, Ill., a cottage for working patients, as well as a new morgue and pathological laboratory. A children's building will also be erected at the Cook County Hospital.

Children's Department for Provident Hospital.—A Children's Department has been established by this institution. The patients will be cared for by the colored nurses. In connection with this department a clinic has been instituted on Tuesdays and Fridays, from 2 to 4 P.M.

Appointment of Dr. Charles Whalen.—The appointment of Dr. Whalen to the Cook County Hospital has been approved by the Board of Commissioners of Cook County. Dr. Warren H. Hunter has been reappointed as County Physician, and Dr. V. H. Podstata has been reappointed as Superintendent of the Cook County Institutions at Dunning.

Cook County Hospital.—It has been suggested that the Council of the Chicago Medical Society take up for thorough discussion the present mode of appointment and of organization of the attending staff of the Cook County Hospital, with the ultimate object of securing for this important institution the advantages of a more permanent and more definitely organized staff than is possible under the elastic system hitherto in vogue. Every high-minded medical man in Cook County has looked forward to the time when the County Hospital will be in the hands of an attending staff organized according to the best ideals, and it is believed that the time is now ripe for an earnest, united effort of the recognized Medical Society of Cook County toward that end.

Influence of Weather Conditions on Mortality.—According to the bulletin of the Health Department for the week ended Dec. 19, 1903, the influence of the weather conditions of the last three weeks or so is already being reflected in the bills of mortality. The death rate for the week is 12.5 per cent. higher than that of the previous week, and very nearly as high as the average December rate of the previous ten years. An analysis of the figures in the statement of mortality indicates clearly that the weather and exposure to it at football games, during the street-car strike, in Christmas shopping, etc., is made responsible for the injuries. Thus, there is a 22-per-cent. increase in the deaths among the aged—those over sixty years. Deaths from the chronic diseases show increases of 10 per cent. each for consumption and heart diseases, of 11 per cent.

for Bright's disease, 65 per cent. for diseases of the nervous system, and 90 per cent. for cancer. The death rate may be expected to increase during the remainder of the month, and those suffering from common colds, catarrhs and similar slight affections of the respiratory system, all of which are almost epidemically prevalent, should exercise more care to prevent the development of tonsillitis, consumption and pneumonia. "Better secure medical attention now than later on in a sick bed," is the advice given by the Department.

GENERAL.

London's War on Rats.—The rat killers report satisfactory progress in their war against the rodents of the London docks. They have killed over 5,000 every month this year. The campaign opened when London had its bubonic plague scare and since then more than a quarter of a million of rats have been put to death. Aside from health considerations, this elimination is commended by the press of London on the ground that rats do an enormous amount of damage in the dock warehouses.

Meeting of Scientists in St. Louis.—The fifty-third annual meeting of the American Association for the Advancement of Science occurred in St. Louis during the present week, with between 700 and 1,000 members present. The first day's session consisted of addresses of welcome and responses. Dr. Ira Remsen, retiring president, called the meeting to order and introduced his successor, Carroll D. Wright. David R. Francis made an address of welcome. Dr. Remsen delivered a fine address on "Progress and Science." As is the custom, the Association was subdivided into nine sections and in these the most interesting work of the session was done.

Arsenical Poisoning in England.—There are some disquieting statements in the report of the Royal Commission on arsenical poisoning, which has been investigating all the circumstances of the extensive and fatal beer poisoning in the English midlands in 1900. It says that the number of persons who suffered was certainly 6,000, and probably considerably greater. Seventy deaths are known to have occurred; but it is believed that a large number of deaths certified as due to chronic alcoholism, cirrhosis of the liver, Addison's disease, or to "alcoholic," "peripheral," or "multiple" neuritis, were really cases of arsenical poisoning occurring before the nature of the epidemic was discovered. It is incidentally mentioned that the period of prevalence of poisoning was attended by a marked diminution of the birth rate in the localities chiefly affected. The report adds that there can be no doubt that a considerable proportion of the beer brewed in some parts of England before 1900 contained noteworthy quantities of arsenic, mainly derived from malt and from brewing sugars, and that the amount derived from malt must have varied greatly in different places. Malt had been shown to be subject to arsenical contamination from the fuel used in the drying kiln, and in a much greater degree when the fuel was gas coke than when other forms of fuel, such as oven coke or anthracite were employed.

Insanity among American Indians.—At the close of the first year's existence of the National Hospital for Insane Indians, at Canton, S. D., the first data ever collected about Indian insanity indicate that forced civilization is responsible for much of it. In its first year half the capacity of the hospital has been taken up by 34 inmates. In a few months the remainder of the rooms will have been taken, and additions will be necessary. But there will still be at large many Indians hopelessly insane, and it is believed that the ratio of insanity will undoubtedly continue to grow. Supt. O. S. Gifford and Dr. J. F. Turner, assistant superintendent and physician of the hospital, agree that the chief cause of insanity among Indians is despondency. Just as with the whites, brooding over troubles and disappointment undermines the Indian mind quicker than anything else. This is manifested in different ways, but most of these manifestations would have been improbable or impossible in the former wild life of the Indian. That brooding should follow when the Indians cannot have the employment of hunting or making visits at a distance and are even prohibited from indulging in their native dances is natural.

Moral Deficients among Children.—The theory of Dr. Still of London that evildoing in children is not "naughtiness" but "moral imbecility" has presented an absolutely new problem to the mothers of Great Britain. It must not, however, be supposed that every phase of infantile peccadillo must be labeled as due to "morbid moral defects." The whole question is purely one of degree. Broadly speaking, the ordinary so-called naughty child is not for the moment, at any rate, worthy of high-class medical consideration. On the other hand, the abnormally naughty child is by a consensus of scientific opinion to be considered as "morally deficient." In the opinion of another physician of wide experience children fell into two groups—the normally naughty and the abnormally naughty. Luckily, the abnormally naughty form a very small minority. He first cleared the ground by saying that children are not born with moral tendencies. The child of three years of age is simply a victim of emotions. It has no morals, but as time goes on accumulated accidents give it experiences which lead it to choose between wrong and right, even upon the lowest possible ground—that right pays and wrong does not. During the growth of some children, however, it is seen that they are not influenced by considerations of this kind. It may be shown in the most subtle way, or it may be perfectly plain to every one. The fact remains that they are not induced to do right by punishment. The difference in some cases is so slight in childhood that the doctor was certain that a large number never showed this taint sufficiently to call for any special comment, but when they grew up and restraints were removed they developed into criminals. One of the great difficulties in dealing with these children was the absence of these special signs, and in view of this the doctor acquiesced in the opinion of Dr. Still that all that could be done was to watch carefully and adopt a system of segregation.

British Cancer Research Fund.—The work of the British Cancer Research Fund, which is now well under way in its laboratories on the Victoria Embankment, London, and at an experimental farm in the country has been divided into four general subdivisions: (1) The experimental work on animals consists of a study of the malignant growths occurring spontaneously among them, and tests as to the possibility of successful inoculations with human cancer. It has already been established that cancer is extremely prevalent among domestic animals, dogs, cats, horses, cows, and pigs being especially prone to it. The inoculability of cancer from one animal to another has been accomplished, thus justifying the claims of several previous investiga-

tors. Experiments are now under way on the farm to determine the rôle which irritation plays in causing cancer. (2) The microscopic work consists of a study of the structure of malignant tumors in the light of their clinical history. Specimens are received from the London hospitals, from hospitals in the British colonies, and arrangements have just been completed for an exchange of specimens with institutions in the United States, France, Germany, Norway, and other countries. It is hoped in this way by keeping in touch with other laboratories to avoid the repetition and resulting loss of time of special lines of research in various parts of the world. (3) The statistical work compares and correlates the facts regarding the occurrence and mortality of cancer in various regions. The figures thus far collected seem to indicate that the alleged increase of cancer is apparent rather than real and is accounted for by greater accuracy in diagnosis. (4) Treatment. In this section the various remedies and proposed "cures" are tested. Thus far the experiments on the various light cures—Finsen, X-ray, radium, etc., indicate that they act simply as caustics. In the case of superficial rodent ulcers, considerable success has attended the use of X-rays. A study of the results obtained by the use of radium does not inspire much hope of its therapeutic future. Regarding a cancer antitoxin, it is stated that a formidable and practically unsurmountable obstacle is the lack of knowledge regarding the cancer toxin, or poison. Until this is obtained, the search for a curative serum is entirely in the dark. The fund still lacks $100,000 of the $500,000 capital which it was calculated would be required to maintain the laboratories. There seems no way in which money could be more usefully spent by wealthy persons for the benefit of mankind. No disease causes more terrible suffering, both mental and physical, and its victims are usually taken at the most productive period of life. The work at the London laboratories is international in scope, and deserves the support of all who can afford to give.

Carnegie Institution and Its Appropriations.—During the year just closed the Carnegie Institution, with its headquarters at Washington, has appropriated liberally to a wide range of scientific investigation. While a large part of the funds distributed by it has gone to researches in astronomy, geology, anthropology, etc., assistance was given to those branches of science more closely correlated with medicine as follows: W. O. Atwater, Wesleyan University, Middletown, Conn., $5,000 for experiments in nutrition; Arthur Gamgee, Montreux, Switzerland, $6,050 for a report on the physiology of nutrition; E. B. Wilson, Columbia University, New York, $1,000 for investigations in experimental embryology in Naples; Marine Biological Laboratory, Wood's Hole, Mass., $10,000.

OBITUARY.

Dr. SAMUEL WOODCOCK, of Manchester, England, died of apoplexy on December 12, 1903, at the age of sixty-four years. Dr. Woodcock was a prominent member of the British Medical Association and a forceful worker in all that pertained to medical politics. He was active in the reconstitution of the association, took a prominent part in framing the Midwives' Bill and many other medical acts that have become English laws.

Dr. DANIEL EMBURY KISSAM died at his home, at Huntington Harbor, Long Island, December 24. Dr. Kissam from 1848 to 1888 practised as a physician and surgeon in Brooklyn. He was a native of New York City, and was born Oct. 3, 1817. He was visiting surgeon to the Brooklyn Hospital, and perfected many contrivances for surgical operations. During the Civil War he volunteered as a surgeon and went to the front.

Dr. HUGH M. WALLIS, a leading physician of Terrebonne parish, La., died at Covington, La., December 27. He was sixty-nine years old, and a native of Kent county, Maryland, but a resident of Terrebonne for forty-one years. He was Mayor of Houma for several terms, Coroner of Terrebonne parish and owner and editor of the Houma *Times*.

WILLIAM NEWMAN, M.D., F.R.C.S., died in the Stamford Infirmary, England, in the seventy-first year of his age. Dr. Newman was for years one of the best known surgeons in the Midlands and held important offices in the British Medical Association.

Dr. WILLIAM H. A. YOUNG, one of Springfield's best-known physicians, was shot through the heart last Tuesday afternoon by a bullet from his rifle, which he was placing in his carriage previous to going hunting. The fatal accident took place just inside the stable doors, which were open, and was witnessed by his wife and several friends who were visiting in the home.

Dr. AUGUSTUS D. RUGGLES of 330 West Fifty-sixth Street, died December 27. He was sixty-three years old, and was graduated from the University of Pennsylvania in 1862. He was a member of the New York Physicians' Mutual Aid Association.

Dr. ROBERT BOOCOCK died at his home, 2,905 Clarendon Road, Brooklyn, on December 28. He was born in York, England, in 1833, and came to this country thirty-three years ago. He was a physician of the homeopathic school, and was also for many years an ordained minister in the Baptist Church. For the past twenty years Dr. Boocock confined himself exclusively to the practice of medicine.

SOCIETY PROCEEDINGS.

THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Sixteenth Annual Session, held at the Piedmont Hotel, Atlanta, Ga., December 15, 16 and 17, 1903.

The President, J. Wesley Bovée, M.D., Washington, D. C., in the Chair.

An address of welcome was delivered by Mayor Evan P. Howell, which was responded to by Dr. George Ben Johnston.

Study of the Prostate and Treatment of Prostatic Hypertrophy.—Dr. G. Wiley Broom, St. Louis, Mo., exhibited a number of hypertrophied prostates that he had removed. The author said that he had made approximately two hundred post-mortem examinations to investigate the condition of the bladder and prostate in each subject. He said it was generally believed by routine prostatectomists that all prostates had a capsule, but this was not true. His conclusions were (1) The position of the urethra in the normal state was always in the floor of the bladder; but in urinary obstruction it was always elevated from an inch to an inch and a half or two inches above the floor of the bladder. (2) He took the position that normally there was no third lobe, but that segmentation took place behind the prostatic fissure in consequence of a hyperplasic process, this process occurring in the direction of least resistance —into the cavity of the bladder. (3) Only a small

percentage of cases of hypertrophied prostate was responsible for urinary obstruction. (4) No matter how large the prostate became, it would retain its functionating capacity. It was not the organ which caused suffering to the patient. (5) By prostatectomy this functionating organ was mutilated or destroyed, and the bladder, which really caused the patient trouble, was left *in situ* without any operation having been performed on it. (6) In only a small percentage of cases could the prostate be enucleated. (7) It was unfortunate that the profession had reached the point of resorting to routine prostatectomy in all cases of urinary obstruction. (8) The commissure and capsule were obliterated in the fibromyomatous variety of prostate. In the adenomatous variety, if complete and permanent drainage was established, the prostate would shrink.

Dr. C. H. Mayo, Rochester, Minn., had operated by the median perineal method in over thirty cases after the manner of the Goodfellow procedure, and had been much pleased with the method and results.

Dr. W. P. Carr, Washington, D. C., had never seen but one prostate where there was any difficulty in peeling it out of its capsule. Cases of hypertrophied prostate should be operated upon earlier, before the bladder became infected. Prostatectomy in healthy men had a very small mortality; but in those who had infected bladders, who had Bright's disease, or atheromatous arteries, it was a serious operation.

Dr. Broom, in closing, deplored the tendency to do routine prostatectomy regardless of the actual pathological conditions of the parts.

Edematous Encephalitis.—Dr. W. P. Carr, Washington, D. C., called attention to a condition of the brain that he had encountered quite frequently when operating for cerebral epilepsy and for suspected cerebral abscess following mastoid disease due to grip. This condition he called edematous encephalitis. It was apparently so much benefited by opening the skull and draining the excessive serum from the brain, that it deserved careful consideration. He reported four cases. It was impossible to say in most cases whether the edematous encephalitis was caused by injury or by the poison of influenza, or whether it was a lesion of epilepsy. He had not been able to find any cases in the literature in which edema was noted as a marked feature. In cases of severe cerebral symptoms following influenza or blows upon the head, where the symptoms persisted or became worse after weeks of medical treatment, he thought that exploration was justifiable in the hope of finding edematous encephalitis or some other condition that would be benefited by operation. In operating for edematous encephalitis he recommended that a large osteoplastic flap be cut with the De Vilbiss craniotome over the site of any injury that might be suspected as a cause, or over some location indicated by the symptoms. If the symptoms furnished no local indication, and there was no local injury, then the flap had best be turned down in a convenient place, say the upper parietal region. The exposed membranes and brain substance should be examined carefully, and if they presented an edematous appearance, a grooved director should be introduced into the brain substance carefully in several places, and the serum drained off until the brain assumed a normal appearance. A small soft drainage tube should be inserted just through the dura into the arachnoid space and left in place as long as there was a copious discharge of serum. This tube might be brought out through one of the small trephine holes made for the introduction of the De Vilbiss instrument, and stitched to the skin after an osteoplastic flap had been replaced. If the head was carefully shaved and scrubbed, and all proper antiseptic precautions taken, this operation was almost free from danger; and if only a small percentage of the serious cases could be cured in this way, the operation would be justifiable. He had been encouraged by his limited experience to believe that surgeons might hope for recovery or great improvement from this operation in many otherwise hopeless cases of epilepsy and of progressive brain disease due to trauma and influenza.

A New Device and Method for Intestinal Anastomosis.—Dr. W. P. Carr said he had devised a method of intestinal or gastro-intestinal union by small silver clamps which he thought were more easily and quickly applied, and that had none of the objectionable features of the Murphy button. The clamps were exhibited. The method consisted in clamping the inverted edges of the gut from the inside, in the manner indicated by drawings which were passed around by the author. The clamps will hold well and make an air-tight closure. They were applicable to any sized intestine or wound. They left a large opening in the lumen of the bowel, and passed out as easily as watermelon seeds. The edge and corners of the clamps were smooth and rounded. They had small teeth to prevent slipping, made by simply indenting the metal; but these teeth were not long enough to pass through the entire thickness of the bowel. The clamp might be applied with any suitable flat broad forceps, but it was better to have a forceps with a slight ridge to keep the clamp from slipping. He had used these clamps in one case of resection of five inches of gangrenous ileum caused by strangulated hernia. The man recovered, and most of the clamps were recovered between the sixteenth and twenty-first days.

Dr. C. H. Mayo said he and his brother (Wm. J.) had operated on many cases of epilepsy and traumatic insanity, and he could corroborate what the essayist had said regarding edematous encephalitis. Treatment by drainage came the nearest to the solution of affording this class of cases relief.

Dr. I. S. Stone, Washington, D. C., mentioned a case, in referring to Dr. Carr's device, in which gastro-enterostomy was performed about a year ago, with the aid of the Murphy button, but the button had not yet been passed. In another case of diverticulum with obstruction the button was used, but the woman was still carrying it with some anxiety. Thus far, however, there were no symptoms of intestinal destruction from the retention of the button. He complimented Dr. Carr on the ingenuity and originality of his device, and said when an opportunity presented itself he would use it.

Dr. Guy L. Hunner, Baltimore, Md., objected to the use of all mechanical devices and favored suturing the intestine; although he thought the simple device exhibited by Dr. Carr would enable surgeons to do intestinal anastomosis rapidly.

Dr. J. Garland Sherrill, Louisville, Ky., advocated suturing the bowel in preference to the use of all mechanical devices. In his intestinal work he preferred silk.

The Surgical Physiology of the Lymphatic System.—Dr. C. H. Mayo, Rochester, Minn., said that a study of the lymphatic system readily explained many normal physiological as well as pathological processes. The subject was deservedly receiving more attention from surgeons who now generally recognized that aside from acting as the general absorbent system, it was constantly engaged in maintaining nutrition as well as defense against pathological processes. All tissues were provided with lymph vessels and glands in direct proportion to their exposure, activity and necessity for repair. The tissues of the body were constantly bathed in lymph, which fluid, similar to and derived from the

blood plasma, must all pass through the lymph vessels and glands. In the glands the lymph was exposed to the direct action of the leucocytes which were there found in great abundance. It was in the glands that infection was checked, and destroyed, or it might possibly overpower the gland and develop local growth. An enlarged gland was an evidence of a local struggle and defeat. The lymph system undoubtedly performed a great function in draining the ductless glands. Considering the lymph supply of certain organs, it was found that the brain was deficient in lymphatics in its structure, the arachnoid serving this purpose upon its surface. Hemorrhages into its structure became cysts from lack of absorption and infections in its substance caused but little temperature or general disturbance except from pressure. The liver and kidney showed the same condition in a less marked degree. The lungs, rich in lymphatics, gave constant temperature from infectious diseases. Chills usually signified the direct delivery of accumulations of infection into a vein. In certain diseases resulting from a loss of equilibrium between the production and absorption of fluids, one set of lymphatics was substituted for another by operation, as in glaucoma and hydrocephalus. When lymphatic conditions were considered in connection with surgical work, it was found that there was a real principle involved in drainage, whether it be internal or external.

Varieties of Drains and Drainage Adjuncts.—(1) Rest by splints, pressure, dressing or bed, to quiet the circulation; (2) by elevation to reduce arterial supply and favor venous and lymphatic return; (3) by massage to break up coagulated exudates and enable the lymph vessels to remove the exuded material; (4) moist dressings favor the escape of exudate from open wounds and also favor the lymphatic circulation in closed injuries; (5) adjuncts to drainage in the use of solutions having affinity for moisture acting by osmosis as glycerine or alcohol; (6) wound drainage could be accomplished by the open method with or without secondary suture; (7) by separate incision; (8) by wicks, capillary or tubular drains, or gauze packs, as mechanical aids.

Early Diagnosis of Cancer of the Uterus.—Dr. F. F. Simpson, Pittsburg, Pa., said the great body of the medical profession saw but a single case of cancer during the time they were treating hundreds of other afflictions, and naturally looked upon that malady as being relatively rare. As a malady, it was infrequent; but as a cause of death its frequency was appalling. Early in 1900 a note was addressed to the health departments of American cities with an aggregate population of ten million, requesting a tabulated statement of deaths from cancer and from all causes during each year of the preceding decade. Statistics showed that of every fourteen people who reached the age of thirty years, cancer would claim one as its victim. Bearing more directly upon the subject of cancer of the uterus, however, was the distressing fact that of every 28 women who passed the age of thirty years, one would be the victim of this disease. The paper was largely statistical, and the author closed by saying that the day was fast approaching when well-informed women of the cancer age would seek protection by regular quarterly examinations. Early diagnosis would then be the rule in cancer of the uterus as it was in appendicitis to-day.

Fracture—Dislocation of the Spine.—Dr. J. Shelton Horsley, Richmond, Va., reviewed the opinions of several authorities on the treatment of this lesion. He recommended that in treatment individual judgment should be used as in other surgical operations. He emphasized the similarity between injuries of the spinal cord and injuries of the brain so far as treatment was concerned, and called attention to the fact that without an operation or a post-mortem examination it was impossible to tell by symptoms alone when the cord was completely destroyed. He advocated the plan of McCosh, to operate in all cases of complete paralysis below the injury unless there was improvement within twenty-four hours after the injury. When the trauma was especially marked, he operated sooner. He pointed out that the danger of delay lay in degenerative changes in the spinal cord which set in soon after the injury. Early operation might arrest this degeneration. He reported six cases, in two of which the injury was received several years before he saw the patient. In one there was a forward dislocation of the axis and atlas from the third cervical vertebra. This was demonstrated by an X-ray picture. The patient had paralysis of the muscles of the arms, body and thighs. There were disturbances of sensation of various degrees over the body and limbs. He reported two other cases in which fatal results rapidly followed the injury. One was from a gunshot wound, and the other was the result of a fall on the shoulder in which there was a fracture-dislocation in the lower dorsal region. The last two cases he operated upon, in one there was an injury at the lower dorsal region where the whole of the dorsal spinal column was dislocated forward upon the lumbar spinal column. The spinous process of the last dorsal vertebra was fractured. The cord was caught between the last dorsal and the first lumbar as between the blades of a pair of scissors. It was not completely crushed as the dislocation was not extensive enough. It was impossible at the operation to reduce the dislocation, so the spinous processes and the laminæ of the last three dorsal vertebræ were removed. This relieved pressure on the cord. The patient died, however, from pneumonia a week later without any improvement in the spinal symptoms. A post-mortem examination showed the wound in an excellent condition, with the cord softer than at the time of operation, and solidification of the whole lower lobe of the right lung, and a part of the middle lobe. In the other case operation was undertaken about a month after fracture of the eleventh and twelfth dorsal vertebræ in a laborer, nineteen years of age. The cord was almost completely gone, there being a few fibers remaining from its anterior portion. The laminæ had been fractured and driven into the canal. One of the articular processes had also been driven into the canal. These were removed, and the wound closed, leaving a small catgut drain. There was no decided improvement in his condition for six weeks after the operation. At this time he urinated voluntarily; two weeks later there was noticeable improvement in both sensation and motion in the thighs. This improvement continued until the present, about three years after operation. His thighs were practically normal as to motion and sensation. Bladder and rectum acted naturally, and his general health was excellent. He could stand with support and walk by having a strong support on each side. His legs and feet were still paralyzed both as to motion and sensation. At present patient weighed nearly two hundred pounds, and was quite comfortable, except for occasional pains in his legs.

Neoplasms, Wherever Situated, Should, if Possible, Be Removed, Whatever Their Apparent Nature.—Dr. Maurice H. Richardson, Boston, Mass., considered chiefly neoplasms of the breast and of the female pelvis in his paper on this subject. The reasons which justified the adoption of the title rule in these regions would apply with certain exceptions to all parts of the body. These reasons, all of which were illustrated by

specific cases, in the author's own experience, were as follows: (1) The uncertainty of the diagnosis, even on the part of the most experienced and the most skilful, made palliative treatment hazardous, especially in the doubtful cases. Several instances were given in which the patient was not operated upon because the tumor was supposed to be benign when, in reality, it was malignant. The error cost the patient the favorable moment for operation. The impossibility of accurate diagnosis in even the most accessible regions of the body was emphasized. Breast tumors apparently benign had proved malignant. Breast tumors benign throughout their principal areas showed minute foci of malignancy. Breast tumors clearly benign had after many years developed a fatal malignancy. So in abdominal tumors, especially the pelvic tumors in women, the difficulties of diagnosis made the apparently benign cases especially dangerous. Many instances were given illustrating the difficulties of diagnosis and the necessity for exploration in even the most favorable cases of presumably benign growths. (2) The dangers of benign tumors becoming in time malignant was emphasized and illustrated by not a few cases in which after years of slow and harmless growth a tumor had suddenly developed evidence of malignancy. Tumors of the breast, of the gall-bladder, the stomach, the uterus, the ovary, and of other regions, had by an acquired malignancy convinced the speaker that the only safe rule of treatment was in all cases thorough extirpation of the tumor as early as possible. (3) The wisdom of exploration in certain apparently hopeless tumors was illustrated by cases in which a benign and easily remediable condition was found, and in which impending death was averted by a safe operation. In this class were infiltrating tumors of the abdominal wall supposed to be hopelessly malignant, but which proved to be tuberculosis of the muscle, aponeurosis; epigastric tumors, apparently cancerous, found to be pancreatic cysts, actinomycosis, chronic pancreatitis, and the like. Pelvic tumors supposed to be malignant and inoperable were proved to be old tubal inflammation, fibroids, ovarian cysts and the like. (4) The essential malignancy of certain areas in the malignancy-inviting nature of certain regions, especially the breast and the ovaries, was especially emphasized. In these regions the tendency of tumors to become malignant made the application of this rule practically imperative. Ovarian tumors, even when apparently benign, were shown to have especially dangerous tendencies to malignant degeneration. (5) In pelvic tumors especially, the benign often masked the malignant. Cases were reported to illustrate the obscuration of a uterine sarcoma by an overlying fibroid. In two recent cases cancer of the ovary was found concealed by an enormous fibroid, and in a third there was found an annular stricture of the sigmoid flexure. The rule of universal extirpation had numerous exceptions. It should not apply to superficial tumors, clearly benign, which could not be removed without great disfigurement; keloids that could not be removed without leaving a broad scar, unless they showed a tendency to ulceration and malignancy; all other benign tumors, which caused needless suffering, disability and disfigurement, whenever their removal was dangerous, or whenever the patient's general condition was unfavorable; and tumors of all kinds in which the dangers and sufferings of removal outweighed the dangers and sufferings of the tumors themselves.

Dr. Henry T. Byford, Chicago, said he belonged to the Chicago Academy of Medicine, whose motto was, "When you see a head, hit it." He thought this would fittingly apply to the removal of tumors as soon as they were seen. A year and a half ago he was called upon to diagnose a tumor in the pelvis about the size of the end of one's thumb, which was situated between the bladder and uterus. The attending physician said that this tumor did not amount to much, and argued against operation. The woman subsequently became pregnant, miscarried at the fifth month, the tumor at this time having attained the size of an egg. He thought it would continue to grow unless removed. No matter whether a tumor was going to become malignant or not, it was a foreign body and should be removed as soon as possible.

Dr. W. P. Nicolson, Atlanta, said early operation, when safe, was to be commended in every case. He related a case of sarcoma of the mesentery in which he had operated, with recovery of the patient. He also narrated a case in which a sarcoma sprang from back of the rectus muscle and infiltrated the whole pelvis. The tumor was removed, with recovery of the patient.

Dr. W. B. Coley, New York, stated that three years ago a patient came to him with a bad cancer of the breast. She had been under the observation of an eminent surgeon, who had been watching the tumor for a year at intervals, telling her not to have anything done until he thought she needed it. The tumor was finally pronounced cancer by this surgeon, but the patient consulted Dr. Coley with a view to having an operation performed. Careful examination disclosed all the characteristics of advanced cancer. An operation was done, but the disease returned within one year, from which the patient died. He thought these growths should be removed without waiting to determine whether they were malignant or not.

Dr. W. P. Carr said that one of the first tumors he had ever removed was a cancer of the breast in a girl of nineteen. He had no idea it was cancer at the time of its removal, but sections proved it to be such. This prompted him to examine all tumors, particularly those of the breast, and he was surprised to find that a great many of the tumors of the breast which he supposed to have been adenoma proved upon microscopical examination to be carcinoma. He thought if surgeons made it a routine practice to examine microscopically all the small benign tumors they removed, they would find many of them to be malignant.

Dr. J. M. Baldy, Philadelphia, said the more experience he had, and the older he became, the more he was convinced that the truly honest man would admit his inability to diagnose accurately many cases of tumors. He supported the essayist in saying that these neoplasms ought to be removed, no matter where they occurred. There were some tumors of the breast that were not malignant. He had removed a number of them, but he thought the vast majority were malignant. In the past year he had re-operated twice on cases of cancer that had been subjected to X-ray treatment, and in one he had operated a third time for the return of the disease after X-ray treatment, although the physician who had used the X-ray had said the patients were doing satisfactorily.

Dr. J. Shelton Horsley mentioned a case of cancer of the breast that was operated on. There was local recurrence, and the patient was treated by the X-ray. After two weeks' treatment with the X-ray the woman began to sink rapidly and soon died. Post-mortem examination disclosed extensive metastases in the brain, liver, kidneys, ovaries, heart, etc. The X-ray had no beneficial influence on this case.

Intestinal Cancer.—Dr. J. G. Sherrill, Louisville, Ky., in a paper on this subject stated that cancer of the intestine, while rare, was more frequent than physicians were led to believe; that sarcoma was much less frequent than carcinoma, and selected especially the small intestine, while carcinoma most often attacked the large bowel. The appendix was the seat of both carcinoma

and sarcoma, although occurring quite infrequently. The literature showed that men suffered from both forms oftener than women. Adeno-carcinoma was the type most frequently seen, while the round-celled sarcoma or the lympho-sarcoma occurred oftenest. The author reported two cases at length of cancer of the intestines. He said that the treatment was to be largely determined by the extent of the involvement. Resection of the intestine and extirpation of the growth offered the patient the only hope of a permanent cure, and this chance, though slight, should be given the patient whenever practicable, as early in the course of the disease as possible. Any of the classic methods might be employed.

Amputation of the Hip Joint for Sarcoma, with a Report of Seven Cases without Mortality.—In a paper on this subject, Dr. Wm. B. Coley, New York, said that the tumor originated in the bone or periosteum of femur in 5 cases, and in the soft parts in two. The age of the patients ranged between six and fifty-six years. In 6 cases Wyeth's pins were used, but in the seventh case the growth extended above Poupart's ligament; pins could not be used, and the external iliac artery was first tied. All of the patients made a good recovery from the operation; yet only one patient survived operation long enough to be called a cure. This was a sarcoma of the thigh in which the mixed toxins of erysipelas and *Bacillus prodigiosus* were used for two months before amputation. In one recent case the patient was still alive without recurrence; in all the other cases death occurred from local or general recurrence in from four months to two years after amputation. Of four other cases of sarcoma of the femur and thigh, treated by high amputation, just below the trochanter, two patients died at the end of four months; one died at the end of 2¼ years, and a third had recurrence in the gluteal region, which disappeared under the mixed toxin treatment, and the patient was alive at present without recurrence, six years afterward. The extraordinary malignancy of sarcoma of the femur was shown by the very small number of patients known to have survived for more than three years after amputation. Butlin was able to find but one case in 68 treated by high amputation or hip-joint amputation. Wyeth in 1901 collected 131 cases treated by hip-joint amputation with ten alive more than three years. Dr. Coley stated that he had personally known of but six cases. In one of these cases (Dr. Bull's) operated up sixteen years ago, a severe infection occurred in the wound, probably streptococcus, and the patient was well six years later. In another case (Dr. Gerster's) the disease was so extensive and so high up that amputation was considered impossible, and the patient was treated with the mixed toxins of erysipelas and *Bacillus prodigiosus* for several months. The tumor disappeared, and the patient was shown at the New York Surgical Society a year ago in perfect health, more than four years after treatment. The better results following amputation in the pre-antiseptic days the writer attributed to the infection that frequently occurred in the earlier period. This fact together with the results referred to, in which the erysipelas toxins were used, he believed sufficient reasons for advocating a systematic use of the toxins after primary amputation as a prophylactic against recurrence. He would not advise such treatment prior to amputation in sarcoma of the femur, on account of the great liability to early metastases, though in a case of sarcoma of the tibia he had been able to save the leg, and the patient was now well seven years afterward. The method of treatment advocated by Mikulicz, namely, resection of the femur, Coley did not think should be adopted as a substitute for amputation. While it was true a fairly useful limb might be obtained by resection, there were no cases treated by this method that had been observed for longer than a year, hence nothing could be said as to permanent cure. The X-ray, Coley believed, should never be used unless the patient absolutely refused amputation. One such case he had treated two years ago (round-celled sarcoma of femur); the tumor apparently entirely disappeared in the femur, but ten months later a large metastatic tumor appeared in the pectoral region, which was partially removed by operation. A little later another very large tumor appeared in the lumbar and iliac regions. Under long-continued treatment with the mixed toxins plus the X-ray, the tumors disappeared, and the patient was alive and well to-day, though by no means regarded as cured.

Diagnosis and Treatment of Gall-stones.—Dr. Mack Rogers, Birmingham, Ala., read a paper on this subject. After referring to the differential diagnosis, he spoke of the operation for the removal of stones from the gall-bladder, saying that where there were no adhesions it was a comparatively easy one, but when the stone was located in the common duct, or extensive adhesions existed, or both, the surgeon had a very difficult condition to deal with. In the hands of competent, experienced men he regarded this operation as one of the safest in the abdominal cavity. The mortality in all cases averaged only about three per cent.

Surgery of Urinary Tuberculosis in Women.—Dr. Guy L. Hunner, Baltimore, Md., reported 35 cases occurring in the service of Dr. Howard A. Kelly and his associates in Baltimore. These patients were all women with an average age at the onset of symptoms of twenty-eight years. The disease was unilateral in 31 of the cases, and it was probably primary in the kidney, as regards the urinary system, in 30 or more of the cases. Thirty-one cases had bladder symptoms at some time in the course of the disease, although only 18 cases had bladder lesions at the time of operation. Eleven of these 18 cases still had some bladder symptoms, and five were known to have bladder lesions, although 9 of the 11 had had systematic bladder treatment. Tuberculosis of the bladder did not heal with the ordinary methods of treatment, and if the disease persisted a year and did not occupy more than half of the bladder, it should be excised. Of 22 ureters examined microscopically, 17 showed tuberculosis, while 5 were chronically inflamed. If a tuberculous ureter remained either in part or *in toto*, the wound usually remained open at least two years, while the removal of the ureter with the kidney resulted in rapid closure of the wounds. Five cases died—three after six and eleven weeks, and two years, respectively, from involvement of the other kidney, and two, in fifteen and six days, because of the operation. Sixty-six per cent. of the patients were enjoying fairly good or excellent health.

Spurious Dysmenorrhea.—Dr. Henry T. Byford, Chicago, read a paper with this title in which he made a plea for a more rational treatment. After naming 25 varieties that were mentioned in the text-books, the author called attention to their disappearance therefrom. Many supposed cases were spurious in character. These had been perpetuated by the physician and cured by the quack. The absurdity of the nasal cure was emphasized and the cures referred to as spurious. Instances of menstruation in the male were quoted. The trend of the paper was to condemn writers for bringing the symptom into the foreground when it should be kept in the background, and for wasting their own time and that of their readers in ridiculous refinements and speculations.

Memorial Address on Dr. W. E. B. Davis.—Dr. Richard Douglas, Nashville, Tennessee, spoke eloquently and impressively of the work that had been accom-

plished by Dr. Davis, and pointed out in a masterly manner the distinguishing characteristics of the deceased.

Diagnosis and Treatment of Congenital Misplacement of the Hip in Infancy.—Dr. Albert H. Freiberg, Cincinnati, Ohio, had been able to ascertain that in several cases children with congenital misplacement of the hip had been late in walking. It was a common experience in mild grades of rachitis that children were late in walking. The usual age of sixteen months was passed by and the rachitic child not only failed to walk, but was usually also unwilling to stand. He had been able to ascertain in several cases and to observe in one that children with congenital luxation stood readily at the usual age for walking, and especially if allowed to support themselves by holding on to some object. It was only when independent effort at ambulation was urged that the child showed its timidity and refused to make the attempt as a normal child would. This period, of course, was gone through by every normal child, but in some cases its long continuance might be attributed to congenital luxation. The length of this period in luxation cases varied greatly, but in every case was finally determined by the child's learning to walk with more or less limping, at which time the diagnosis was usually made and was of no further interest in this connection. In some few instances mothers observed these things, and possibly also that the apparent breadth of pelvis and perineum was unusually great. It was, therefore, urged that in the presence of any of these signs which had been referred to, attention be paid to the possibility of congenital luxation, and that in the event of any doubt the X-ray be resorted to as a final means of precision. Experience had abundantly shown the feasibility of operative procedure after the age of one year, and that the results amply justified the great additional care which was necessary to prevent the dressings from becoming soiled in so young a patient.

The Progress of Ureteral Surgery.—Dr. J. Wesley Bovée, Washington, D. C., President of the Association, selected this title for his Presidential Address. After referring to the deaths of Drs. W. E. B. Davis, George J. Engelmann, and J. McFadden Gaston, he spoke on the surgery of the ureter, giving its history and present status. The treatment of ureteral calculi first claimed attention, since the diagnosis and treatment of this condition were very much studied at the present time. The employment of the X-ray was the simplest procedure known for purposes of diagnosis, and were it accessible at all times and completely reliable, no other method would be comparatively valuable. Unfortunately, such conditions as calculous anuria might render a patient in a secluded place so ill that this method of investigation was necessarily precluded. Moreover, calculi might be of sufficient size to block the ureter and give no shadow in the radiograph. For this reason especially, other plans of examination should be employed, although the necessity of constant manipulation of the ureter was a *sine qua non* to dexterity in treating other conditions of this structure. Palpation would ever have its important position. Exploration was an important method in such investigations. Tubular calculi might escape discovery by this plan. The wax tipped bougie, suggested and used by Kelly was especially sensitive, and no doubt if it touched a calculus it would receive a telltale impression. In the treatment of ureteral calculi the proper plan was extraperitoneal ureterolithotomy as infected urine was usually associated with this condition and easily produced peritonitis, if permitted to come in contact with the peritoneum. If pus was not present, the establishment of ureterocutaneous fistula would seldom be necessary, though careful drainage of the wound would be advisable. This rule applied to every part of the duct. He was firmly convinced the ureteral wound should be made longitudinally whenever possible, and sutured after lithotomy. If much necrosis of the ureter was manifest, as had often resulted from the impaction of a calculus, each case should be treated according to the judgment of the surgeon, and such modifications as resection or exsection, with uretero-ureteral anastomosis or ureterocystostomy might rarely be required. Frequently pyonephrosis accompanied calculous ureteritis. Incision and drainage, and probably nephrolithotomy would be needed in addition. The routes employed depended upon the location of the calculus, the bladder, vagina, or loin being selected. He could only endorse the rectal route, as employed by Ceci, when examination revealed a calculus ulcerating into the rectum or threatening to do so.

For ureteral fistula nothing need be done unless obstruction of the duct below the fistulous opening existed. In such a case the caliber of the canal must be restored. Usually the fistula would then close spontaneously, although so much cicatricial tissue might be deposited about the opening as to prevent closure. Suture or perhaps resection might be required in that case.

Dr. Bovée then referred to subcutaneous injury of the ureter, saying that no treatment was advisable unless evidence of extravasation of urine or of ureteral obstruction existed. For partial division of the ureter suturing should be applicable. Abnormal ureteral terminations of congenital origin might be corrected by ureterocystostomy, usually by the vaginal route. Fortunately in these cases the ureter was abnormally long, and therefore the difficulty was much less than was the same operation for other indications. The ureter might be removed in whole or in part tor tumors, tuberculosis, and malignant disease. In 1899 he was able to collect from literature about 24 cases of partial or complete ureterectomy. Now the number had increased to nearly one hundred. In complete ureterectomy or nephro-ureterectomy in women probably the loin and vaginal incisions constituted the best plan. In his last case he separated the lower two inches through a vaginal incision, and then separated and withdrew the kidney and ureter by the loin route. This he believed to be the best of all. For ureteritis the treatment had been largely of irrigation and topical applications. He had been disappointed in this work and had grave doubts of its being the best. Probably the violence done to the lower part of the ureter by this instrumentation counterbalanced the benefits. He had had a few cases of trigonitis that had come to him after ureteral irrigations were said to have been made. He had in consequence been led to speculate as to whether a non-alcoholic, non-nitrogenous diet with diuretics and rest in bed might not be superior treatment for simple ureteritis.

Pus Collections in the Pelvis.—Dr. C. N. Chavigny, New Orleans, La., discussed this subject, in which he reported three cases of mistaken diagnoses.

The Technic of the Vaginal Method.—Dr. J. Riddle Goffe, New York, said in his own hands the scope of the operation, namely, the conditions to which it was applicable, was steadily widening. It was no longer confined, on the one hand, to simple puncture and drainage, nor limited, on the other, to the radical operation of hysterectomy. All the intermediate procedures that were called for by the multifarious pathological conditions found in a woman's pelvis found their most direct route through the vagina. There were two vaginal incisions through which the pelvic cavity could be reached; one, posterior to the cervix into Douglas' pouch, and the other anterior to the cervix, separating the bladder from the uterus and opening up to view and touch the entire contents of the pelvis. The latter was the one which afforded the greater facilities for operative procedures.

and the one which he depended upon almost exclusively. The posterior incision was frequently used in connection with it, to afford additional opportunity for the purpose simply of securing drainage and in some cases for manipulation. The procedure was described. The simplest application of the vaginal method, and the one that probably commended itself most universally to the profession, was incision and drainage of pelvic abscesses. On general principles he believed all were ready to subscribe to the dictum that so far as the patient was concerned, any operation that could be as well done through the vagina as through the abdominal incision was better done along the vaginal route. The possibilities of this work would undoubtedly vary with individual experience, but the more experience he had, the broader became the field of application, until it seemed to him that any pathological condition that was confined to the true pelvis could be dealt with as satisfactorily, with as permanent results, and with far greater safety to the patient through the vaginal incision than through the abdominal incision. The author's cases had embraced every variety of disease from simple retroversion, with or without adhesions, to prolapsed and cystic ovary, unilateral and bilateral salpingitis, ectopic gestation, fibroid tumors of the uterus and dermoid cysts. The method lent itself to every form of conservative work upon the uterus and its appendages that had been suggested in the trend of recent modern gynecology. The successful application of it required patience, experience and skill, but when once the profession had been convinced of its superiority, he believed it would steadily and rapidly grow in favor and become the accepted method for the man who practised the specialty of gynecology.

Tuberculous Ostitis of the Knee.—Dr. A. R. Shands, Washington, D. C., said that the management of a case of white swelling could be embraced in the terms immobilization and protection in any and all stages of the disease. The indication was to preserve the function of the joint as far as possible, to arrest the progress of the disease, to prevent and correct deformities. Immobilization and protection with the best hygienic surroundings and the best tonic treatment appropriate to the individual case would best accomplish the indication just mentioned. If the diagnosis was made early and this line of treatment faithfully carried out, a large percentage of cases would yield very favorable results, many recovering with little or no disability. When it became necessary to incise and drain a joint, it should be done thoroughly and good drainage should be kept up just as long as there was any discharge. When the infection of the joint was due to an ostitis that was near the surface of the ends of the bone, often the diseased bone sloughed away and when it could be easily located and curetted, most excellent results were obtained. A case was cited in point. The operation of excision of the knee should never be done in children, except in extreme cases, and even then the author believed that amputation would be best, for an artificial leg is more useful than such a leg as a child would have after excision.

Bilateral Diffuse Virginal Hypertrophy of the Breasts.—Dr. George Ben Johnston, Richmond, Va., reported the case of a white girl, virgin, aged sixteen years, four feet ten inches tall, weighing 112 pounds, who had this disease. The breasts hung from the chest wall at about the fourth rib and reached to a point just above the symphysis pubis; the nipple was flattened and stretched. The substance was soft and of similar consistence to that of a well-nourished multipara's breast; the glandular masses scattered throughout were distinctly palpable. The breasts were almost symmetrical, with the exception of a lobular division at the base of the left breast of the same general structure as the main tumor. Two small scars near the right nipple indicated the site of former abscesses. The anteroposterior circumference of the left breast was 19¼ inches; the anteroposterior circumference of the right breast was 21¼ inches; the superior inferior circumference of the left breast was 32 inches; and of the right, 31 inches. Operation was performed under ether anesthesia, and occupied thirty-five minutes, the left breast being removed first, followed immediately by the right. The breast was held above the field of operation, and the amputation carried on as rapidly as the vessels could be caught by assistants. Healing was by primary intention, and the patient was up and about in six days.

Dr. George H. Noble, Atlanta, reported a case of excision of the psoas magnus muscle for sarcoma.

The Differential Diagnosis of Syphilis and Cancer of the Vulva—Dr. Barton Cooke Hirst, Philadelphia, read a paper on this subject. After referring briefly to the differential diagnosis of these two affections, the author reported the case of a woman, twenty-eight years of age, single, who had never been pregnant. She denied ever having led an immoral life, and the possibility of venereal infection. Ten years ago she was operated on in the Pennsylvania Hospital for hemorrhoids and fissure *in ano*. The wound of the operation did not heal properly. More than a year ago the patient noticed an ulcerated condition of the vulva, and a short time afterward incontinence of feces, followed soon by incontinence of urine. For two years past there had been amenorrhea. On a specular and digital examination, a fistula between the fossa navicularis and the rectum was discovered. The whole urethra was gone; there were three little tubercles at the neck of the bladder, these being all that was left of it. The vagina above the neck of the bladder was perfectly healthy. The cervix was normal, except that it was atrophic, as was the whole uterus. The case, at first sight, looked like an inoperable epithelioma of the vulva. It was pronounced to be so by one of the most experienced dermatologists in Philadelphia, to whom it was shown. But there was none of that extensive infiltration and elevation of the skin surface around the edges of the ulceration, such as was seen in an example of extensive epithelioma of the vulva, considerably advanced, but not yet inoperable. Moreover, numerous pieces of tissue from different places in the ulcerated area showed nothing characteristic of cancer. There was everywhere the most extensive round-cell infiltration and necrosis of tissue. The microscopic study, as well as the macroscopic appearance suggested syphilis in the ulcerated gummatous form as the most likely possibility, epithelioma being excluded. Accordingly the patient was put on specific treatment in spite of her negative history, and the entire absence anywhere in it upon her body of signs indicating an old syphilitic infection. The treatment was given up within a week, as the patient was severely ptyalized and could not endure large doses of potassium iodide. Lupus next suggested itself. On two separate occasions, under anesthesia, 12 or 15 pieces of diseased tissue were removed for microscopical examination. No tubercles or bacilli could be discovered anywhere. Inoculations in animals were negative. The urine contained no tubercle bacilli. The bladder itself was healthy. There was a response to the tuberculin test, but the woman had a patch of consolidation in the apex of one lung. Meanwhile the patient was given X-ray treatments every other day for eight to ten minutes. Within three weeks the external ulceration was healed. The local appearance at that time showed great improvement. Two weeks later the rectovaginal fistula spontaneously closed under the continuance of the X-ray applications. Nothing remained of the original disease, except the absence of the urethra

and an elephantiasic condition of the labium majora. The former had been corrected by urethroplasty. He had not yet joined the new urethra to the opening in the bladder, so that the establishment of continence of urine was still doubtful, but he was quite hopeful of making the patient eventually entirely comfortable.

Symposium on Appendicitis.—Dr. George R. Dean, Spartansburg, S. C., read a paper on appendicitis, saying there was not a surgeon who could tell in any given number of cases, in the beginning of the first attack, which ones would have severe attacks, and which light ones; which ones would die without operation, and which ones would recover permanently, which ones would recover to have repeated attacks, or which ones would recover cripples and never have another attack. The surgeon should be called in all cases of appendicitis. He considered it a surgical disease, outside of the pale of the physician, and when it was once discovered there was only one proposition to be made—namely, to urge operation at the earliest possible moment.

Appendicitis and Its Relation to Pelvic Inflammations.—Dr. J. M. Baldy, Philadelphia, was able to appreciate the reasons, although not agreeing with them, of the class of surgeons who removed the vermiform appendix as a routine practice as a prophylactic measure, but was unable to follow the reasoning of that class who adopted the practice of removal on the ground that the condition of adhesion implied appendicitis or future danger of this disease. Ninety-five per cent. of the mixed class were in origin cases of pelvic inflammatory disease, and the adhesion of the vermiform appendix was a mere coincidence due to inflammation of contiguous serous surfaces, as was so commonly the case of adhesion of intestines in pelvic inflammatory diseases. His experience had led him to differ with those gentlemen who held that appendicitis generated pelvic inflammatory disease, or that pelvic inflammatory disease caused appendicitis. The two diseases were rarely associated, and only then as a coincidence. He was firmly of the opinion that the one never causes the other. In all his experience he had not seen a single case in which, having found pus in a Fallopian tube, had he found pus in the involved vermiform appendix; nor had he found a perforating or gangrenous appendix in such a case. On the other hand, where he had found a perforated or gangrenous vermiform appendix, or one which contained pus, either in its cavity or enclosed in its walls, had he ever noticed pus in a Fallopian tube or ovary. Should he meet with such a condition it would appear to him that the two diseases existed as a coincidence independent of each other, as far as direct infection from one to the other was concerned.

Retroperitoneal Infection a Result of Appendicitis.—In a paper on this subject, Dr. I. S. Stone, Washington, D. C., said that it was our plain duty in certain septic cases to investigate the retroperitoneal space with the same care as the cavity of the peritoneum. First, one should consider every delayed case with anxiety, lest there should be retroperitoneal infection. Second, one should be careful to give a guarded prognosis in every case of appendicitis ushered in by or complicated by chills or any symptoms of sepsis. Third, if operating in such cases, one should consider retroperitoneal infection as already started, and act accordingly. The discovery and proper treatment of such infection was quite as important as the usual intraperitoneal technic. In view of the possibilities of retroperitoneal infection, the surgeon assumed great responsibility by advising non-intervention in appendicitis, and while one would often advise delay, when he believed the lesions were strictly intraperitoneal, yet it would appear to the writer that such a course was unsafe and should be condemned when there was reason to fear complications.

Short Incision in Appendicitis.—Dr. Robert T. Morris, New York, said the beginner in surgery was inclined to make incisions that were too short, rendering his work more difficult and very likely incomplete. With the establishment of confidence in his resources, the tendency was to make freer and bolder incisions. The surgeon could not do good work, particularly in abdominal surgery, if he began his work with incisions that were too short. He could not do the best work if he continued to make incisions that were too bold or too free. After one had acquired a certain amount of skill in technic, he could return to the shorter incisions, which would allow the patient to escape with the least possible attack of incision. Even a bear had been known to die from too much incision, and in dealing with patients the incision was of some consequence to them. With long incisions there was more shock; more adhesions, first, because the exposure of the peritoneum through a long incision excited greater inflammatory reaction, and this resulted in more peritoneal adhesions, which must be disposed of, or which might remain to make the patient lifelong trouble. Second, the longer the incision, the greater the danger of infection from the aerial bacteria. With long incisions the patient's general resistance was interfered with. He would make this statement, however, that the surgeon should make as long an incision as he felt was necessary, and by no means be guided by the idea that he was to conform to any length of incision, the idea being that if one could allow the patient to escape with a mild attack of incision, he should do so.

The Significance of and Management of Paralysis of the Bowel.—Dr. Geo. S. Brown, Birmingham, Ala., emphasized the views held by the surgeons of the past generation, that paralysis of the bowel in the presence of inflammation of the peritoneum was to be regarded, not as a pathological condition to be combated, but rather as nature's way of allowing the plastic exudate to form adhesions, the use of which was to confine the infection to as limited a field as possible. He held that it was not the paralysis, but the overdistention of the bowel, that should be fought. By following the plan of keeping the upper uninflamed portion of the bowel quiet, until the inflammation subsided, rather than attempting the difficult or impossible feat of reviving the inflamed and paralyzed portion by the use of purgatives, he believed he would cure many or the majority of the cases of diffuse peritonitis with which the surgeon had to deal. This rest treatment should be applied after the offending appendix or tube had been removed, and the infected site properly treated and drained. It seemed to him that if the Ochsner plan of treatment would tide over a patient with a gangrenous appendix, such a patient could have a much better chance if that appendix were removed, and to the Ochsner treatment were added the tight abdominal binder with water to relieve thirst and wash out the stomach, if there was vomiting, together with opium *ad libitum*, to relieve pain and keep down peristalsis. He believed that many patients died with all the symptoms of general peritonitis following operations for appendicitis where autopsies would show that the inflammation had been walled off, and that death was really due to the activity of the upper bowel, due to the presence of food or purgative, which, being unable to pass the lower paralyzed portion, set up a return wave of peristalsis, causing regurgitant vomiting and death from exhaustion and sepsis. He related two cases in point. Both patients had high fever, great distention and gulping fecal vomit, and the autopsies showed that neither had general peritonitis. One of these patients had been operated upon, the other had not, but both had been given large doses of purgatives. In a total experience of ninety cases of ap-

pendicitis he had had 66 pus cases, 24 of which had been treated by the plan of starvation, except as to water, prolonged irrigation of the stomach before leaving the table, a tight abdominal binder and opium. Eighteen of these patients had more or less diffuse peritonitis, and 12 of these were so severe that they had to be extensively disemboweled in order that adhesions could be broken up and septic material wiped away. Two of these only died. These might have recovered had they been tided over without operation, but as they were both *in extremis* at the time, probably the only thing saved would have been the reputation of the surgeon. Of five other deaths occurring in the ninety cases, two were due to subdiaphragmatic abscess rupturing into the lung, one to regurgitant vomiting, due to the presence of a large quantity of castor oil in the bowel, which was not washed out, and two early cases where abscesses that had already set up a diffuse peritonitis were merely incised.

Septic Thrombosis of the Femoral Vein Following Influenza.—Dr. D. F. Talley, Birmingham, Ala., reported a case of septic thrombosis due presumably to influenza from which the patient was recovering when the phlebitic trouble arose.

Five Recent Successful Laparotomies for Gunshot Wounds of Abdominal Viscera, Including One with Twenty-eight Perforations of Intestines and Mesentery.—Dr. Robert W. Johnson, Baltimore, Md., read a paper with this title, in which he reported five cases The first was one of gunshot wound of the stomach and liver; laparotomy, with recovery; second, a gunshot wound of the liver; laparotomy, recovery. Third, gunshot wound of the liver; laparotomy, recovery. Fourth, gunshot wound of intestine, laparotomy, recovery. The fifth case was one of gunshot wound of the intestines, in which there were 17 perforations of the gut, 11 of the mesentery. The patient was a colored boy, aged seventeen years. While watching an election row he was shot in the abdomen. When put on the table he presented the appearance of a strong, well-developed negro, composed in manner, but suffering from profound shock. There was no pulse at the wrist, and collapse seemed imminent. Salt solution was injected into the thighs and strychnine given hypodermically. A wound from a 32-caliber ball was found in the left side, just above Poupart's ligament, which, after washing, was found to go directly into the abdominal cavity. A median incision was made below the umbilicus and the belly found to be full of blood. Through this incision the gut was drawn out on to warm towels and seventeen perforations of the small intestine, and eleven of the mesentery, were successfully closed by silk Lembert sutures. Patient had no setback after the operation, and was discharged well three weeks after injury was received.

Cases of Intestinal Obstruction Treated by Resection.—Dr. W. H. Doughty, Jr., Augusta, Ga., reported three successful cases of resection of intestine for obstruction due to gangrenous umbilica hernia, volvulus, and intussusception, respectively. He presented these cases briefly as a contribution to the statistics of an operation, the mortality of which was very high. One of the cases was rather unique, so far as the author knew, in that the strangulated loop of intestine in the hernia was a part of a greater segment which had been strangulated by volvulus. It was likely that the descent of the herniated coil took place shortly after the occurrence of the volvulus, and its strangulation was occasioned by the congestion which followed the latter. The almost invariable fatality which attended the operation he attributed to the toxemia that was induced by gangrene of the intussusceptum. In one case, however, which he outlined, in spite of the unmistakably gangrenous patches upon the intussuscipiens and involving even the mesentery, the patient, though far from being in a satisfactory condition, stood the operation fairly well, rallied promptly from the depression which attended it, and recovered without interruption.

Free Growths in the Tunica Vaginalis.—Dr. Edward A. Balloch, Washington, D. C., reported the case of a colored boy, sixteen years of age, who came under his care in December, 1902. Family and personal history threw no light on the case. There was no history of injury. Present trouble began eight years before, as an enlargement in the upper part of the right of the scrotum, which continued to grow painlessly from that time onward. Examination showed a scrotum reaching nearly to the knees and measuring twenty-one inches in circumference at its largest point. Both testicles and both cords could be made out and felt normal as to size, shape and consistence. There was no fluid in the scrotum, but a peculiar gelatinous, flabby feeling of the scrotal tissue. Three separate tumors were felt in the right side of the scrotum. The growths were freely movable in relation to cord, testis, and scrotal tissues. The diagnosis of fibroid growths in the tunica vaginalis was based partly on the history of a slow, painless growth, and absence of ulceration and fistulæ, excluding cancer, syphilis, and tuberculosis, and partly on the physical characteristics of the growths, together with a keloid behind the right ear, which was interpreted as indicating a tendency to fibromatosis in the patient. Operation, Dec. 15, 1902, showed the tunica greatly enlarged and thickened, and converted into a gelatinous mass. The upper tumor ran into the inguinal canal and was attached there by a pedicle. The other two showed no distinct points of attachment. All the tumors were enucleated and the thickened tunic removed. The testicle was removed accidentally in dissecting out the tunica. The tumors weighed 38 ounces, and the tunica 20 ounces. The specimens were shown. The report of the pathologist showed that the growths were soft fibromata, with areas of fatty and myxomatous degenerations. The testicle also showed areas of beginning myxomatous degeneration. The pathology of the condition was considered briefly, the conclusion being reached that the growths had their origin in the subserous connective tissue. Examination of the literature showed but one case at all resembling the one reported, although there were several reports of minute fibrous growths on the tunic following hydrocele treated by the injection of iodine.

Dr. J. McFadden Gaston, Jr., Atlanta, Ga., dealt with the complications encountered in the surgical treatment of the testicle.

Extrauterine Pregnancy.—Dr. T. J. Crofford, Memphis, Tenn., reported a case and exhibited a specimen in which the gestation sac was so thoroughly developed and so strong, that it was enucleated without the loss of any blood. The sac was completely intact all around the fetus. The operation was performed before the class. The speaker supposed it to be a parovarian cyst. After the specimen was removed, it was thrown upon the floor. When the patient was put to bed, the sac was slit open and out came the fetus. When the abdomen was opened in this case, the head of the cecum was found in front and adherent to the anterior abdominal wall. It was found necessary to remove the appendix.

Colloid Carcinoma of the Rectum with Excision by the Combined Vaginal and Inguinal Routes.—Dr. J. Horace Whitacre, Cincinnati, Ohio, reported a case of colloid carcinoma of the rectum which presented unusual pathological and clinical features. After detailing a complete history of the case and describing the operation, the author stated that his chief reason for presenting the case was the unusual nature of the primary tu-

mor. He had never before seen a carcinomatous tumor of the bowel which had developed as a hard, uniform thickening of the entire circumference of the tube. The tumor involved the wall of the rectum to almost a uniform degree for six inches in its length, and the organ was transformed into a tube that might very well be compared to a flattened lead pipe with very thick walls. The tube was very rigid and non-collapsible when in a fresh state. The lumen of the tube was unfortunately firmly packed with gauze before it was placed in Kaiserling's preservative fluid, and had been thereby dilated to almost twice its actual size during life. A second point of interest was the strong naked eye resemblance to tuberculosis. The minute bodies which were scattered over the pelvic peritoneum could not be differentiated from miliary tubercules. Large caseous lymphnodes were found in the hollow of the sacrum. The great predominance of fibrous tissue, the uniform involvement of a long segment of the bowel, and the appearance of minute nodules resembling miliary tubercles in the primary tumor of the rectum all spoke for hyperplastic tuberculosis of the bowel. A third point worthy of mention was the exceedingly rapid development of the solidly carcinomatous ovarian tumors from half a dozen minute miliary metastases on the peritoneal surfaces of each. These tumors were friable and almost jellylike, as were all of the metastases, whereas the original tumor was as hard as cartilage.

Pneumatic Rubber Suit.—Dr. George W. Crile, Cleveland, Ohio, said that the pneumatic rubber suit was constructed of a double layer of specially made rubber, which, when inflated, exerted a uniform pressure upon the surface, constituting an artificial peripheral resistance. It was so constructed that one or more limbs or the abdomen might separately or in combination be subjected to pressure by inflation by means of a bicycle pump. The air valves were so adjusted that the rate of decompression might be completely controlled. The effect of the suit upon the blood pressure might be checked by means of a sphygmomanometer. The general blood pressure might be varied at will within a range of 25 to 75 mm. of mercury. The rise had been sustained as long as twelve hours. In operations upon the head and neck, which were likely to be attended by dangerous shock and collapse, the pneumatic suit was put on the patient prior to operation. By inflation and deflation the blood pressure might, within certain limits, in the heaviest operations, be maintained at a given level. In a laryngectomy with extensive resection of lymphatic-bearing tissue of the neck moderate shock developed. The blood pressure was raised by means of the rubber suit, which soon sprung a leak; a marked fall in the blood pressure following. During the experimental stage the influence of the pneumatic suit upon the blood pressure was strikingly demonstrated in a pulseless case in which the blood pressure was raised to 110 mm. Other cases were reported, showing the value of the pneumatic rubber suit in cases of shock and collapse.

Resuscitation of Animals Apparently Dead.—Dr. Crile also read a short paper on this subject, giving a summary of experimental data. When asphyxia caused failure of the heart and respiration, vigorous artificial respiration usually restored their function when administered within a few seconds. It was effective in an inverse ratio to the time that had elapsed; it was rarely effective after forty seconds. By the addition of saline infusion a larger proportion of animals could be resuscitated after the lapse of a little longer time. Rhythmic pressure upon the heart, either through the thorax by pressure upon the ribs over the heart or direct pressure within the thorax was also an aid. The effect of the traumatism to the heart by the direct method partially counterbalanced the benefit from this measure. Nitroglycerin, alcohol and digitalis were useless; rapidly alternating the posture, head up, then head down, was not effective. Suspending the animal head down and making rhythmic pressure upon the heart was an effective method. This method gave the brain the advantage of gravity; it provided a moderate artificial circulation, as well as respiration. It could be promptly applied. The addition of saline infusion increased the effectiveness of the method. Animals apparently dead for periods up to fifteen minutes were resuscitated by the combined effect of artificial respiration, rhythmic pressure upon the heart, and the infusion of adrenalin. When the blood pressure had risen to 30 or more mm. Hg, the heart began to beat and the blood pressure was rapidly restored. The return of respiration was signaled by a short, almost imperceptible movement of the diaphragm, the respiratory action becoming gradually stronger and more frequent. The conjunctival reflex returned early. Some of the experiments failed on account of too great elevation of the adrenalin bottle; some on account of an overdose of adrenalin; several were only partially successful, owing to the great dilution of the adrenalin. Adrenalin, when injected directly into the chamber or into the wall of the heart, caused fibrillar contractions, after which the heart could not be resuscitated. After final cessation of the heart, by employing manual compression of the heart and infusing adrenalin, the blood pressure could be raised even higher than the normal. Respiration in some instances was partially restored. Experiments in which saline infusion was substituted for adrenalin, and which were unsuccessful, were promptly successful on adding adrenalin. In a patient with crushed skull, and whose heart had ceased beating for nine minutes, resuscitation of the heart for thirty-one minutes by this method was made. During the operation for the elevation of the depressed bone, the patient moved his head.

Officers for the Ensuing Year.—The following officers were elected: President, Dr. Floyd W. McRae, Atlanta, Ga.; First Vice-President, Dr. Geo. S. Brown, Birmingham, Ala.; Second Vice-President, Dr. J. Shelton Horsley, Richmond, Va.; Treasurer, Dr. Chas. M. Rosser, Dallas, Tex.; Secretary, Dr. W. D. Haggard, Nashville, Tenn. Birmingham, Alabama, was selected as the place for holding the next annual meeting; time, Dec. 13, 14 and 15, 1904. Dr. John D. S. Davis, Birmingham, was selected as the Chairman of the Committee on Arrangements.

The Council made a report to the effect that the former action of the Association in appropriating $2,000 to a memorial in Birmingham, consisting of a ward bearing the name of the Association in the City Hospital of Birmingham, be rescinded, and that in lieu thereof $2,000 be appropriated to the erection of a monument to the memory of Dr. W. E. B. Davis in Birmingham. The report of the Council was adopted.

BOOK REVIEW.

Nurses' Guide to Surgical Bandaging and Dressings. By Wm. Johnson Smith, F.R.C.S. Principal Medical Officer, Seamen's Hospital, Greenwich. J. B. Lippincott Company, Philadelphia; the Scientific Press, Limited, London.

Although intended for nurses, this would make an excellent volume to put in the hands of the medical student, as his first introduction to the underlying principles of asepsis, the treatment of wounds, etc. It is interestingly written, like most English books, and profusely illustrated, especially in the section on bandaging, and we can heartily recommend it.

ORIGINAL ARTICLES.

THE MORTALITY OF APPENDICITIS.*

BY FREDERIC S. DENNIS, M.D., F.R.C.S.,

OF NEW YORK;

PROFESSOR OF CLINICAL SURGERY, CORNELL UNIVERSITY MEDICAL COLLEGE, NEW YORK CITY, ATTENDING SURGEON TO BELLEVUE AND ST. VINCENT'S HOSPITALS.

IT has been difficult for me to select a subject about which much has not been written by the members of this society. The only solution of the problem has been to bring before you a part of some great subject, and dwell briefly upon that particular point to the exclusion of the subject in general. In accordance with this idea, I have chosen for my paper this evening, the mortality of appendicitis, its cause and limitation. There is probably no surgical disease about which so much has been written as appendicitis. The subject is trite and threadbare in many respects. There is little to be learned in regard to the etiology, symptomatology, and diagnosis of the disease. The operative technic can be but little improved upon in its present state of perfection. The mortality under proper antiseptic and aseptic conditions is so low, that in the nature of the disease it will never in all probability, be brought much lower. The writer's apology in offering some remarks upon the mortality of the disease, is the hope that others will contribute to this part of the subject, since in this way only can the profession arrive at a conclusion as to the progress which modern surgery has made in this direction. It is only by a careful study of the mortality under given conditions, that any improvement can be made in the direction of diminishing in the future, what now seems to be the lowest mortality that can be obtained. The percentage in these days of aseptic surgery in this abdominal operation, is less than the percentage in the simple amputation of the finger in the pre-antiseptic days. It would seem that surgery had reached its climax in regard to mortality in operation for the relief of appendicitis, yet the time will never come when there will be no death rate. Complications are certain to arise that are beyond the control of the surgeon. Crural thrombosis, intestinal obstruction, acetonemia, embolism, shock of operation, intercurrent affections, all afford examples to show that some mortality must always exist. It is with a view of possibly further reducing the small mortality, that this contribution is made. If a fraction of a per cent. can be gained in the reduction of the mortality, it is an advance in the right direction. The experience of surgeons during the past few years has demonstrated new methods, has pointed out new ways, and has discovered new facts, all of which tend to reduce the mortality. It seems now the only thing that is left is to combine the various views of experienced surgeons into some uniform plan of treatment, in order to produce the best results. There appears to be a fair concensus of opinion as to the advisability of removing the appendix in those cases where the attacks have been multiple, or even solitary. There is also a uniformity of opinion in reference to an operation in diffuse peritonitis as the only measure to save life. There is likewise no difference of opinion as to the propriety of an operation in abscess cases in order to afford the patient the best chance for recovery. There is however, some variation of opinion among the best surgeons as to the necessity of immediate operation in cases of catarrhal appendicitis. Some surgeons advocate an operation in all cases at once, even within the first twelve hours, other surgeons whose experience is just as extensive, counsel delay if the attack is mild, with the expectation of removing the appendix in the interval, since this operation is safe in the hands of a well-trained surgeon. It is in this type of cases that surgeons are not in perfect accord. The question that forces itself upon us for a solution is: Can the mortality of the disease be reduced by immediate operation in all cases, or by delay in mild cases, and the removal of the appendix after the attack has subsided. It has been proved by the accumulated experience of surgeons that interval cases have practically no mortality. It has been shown also that operations during an attack, even though early, have been attended by some mortality. As to which of these two courses to pursue, in all cases it seems to the writer that the only safe plan is to decide each case upon its merits. There may be special reasons when an immediate operation in a given case is the better plan of procedure, and likewise there may be special reasons in another case why delay is the better course to pursue. Such factors as environment, the presence of a skilled surgeon, capable assistant and good nurse, proper sterilization, all enter into the question as to the wiser course to pursue in a given case. It is only by an exhaustive study of all facts in each case, that a plan can be adopted that will afford the patient the best chance for recovery which is tantamount to saying with the least possible mortality.

The mortality in appendicitis in all cases under medical treatment is about 16 per cent., with 30 per cent. of relapses, while in diffuse suppurative peritonitis it is almost uniformly fatal. The mortality in appendicitis in all cases under surgical treatment is about 4 per cent., and with no relapses, and in diffuse suppurative peritonitis the mortality in the published statistics is from 31

* Read before the Medical Society of the County of Kings, December 16, 1903.

per cent., the lowest, to 91 per cent., the highest, and in the writer's eleven consecutive cases of diffuse suppurative peritonitis the mortality was zero. It is stated by Fowler that "13 per cent. of all cases develop diffuse peritonitis; but in order to save 13 per cent., 100 successful laparotomies must be performed," and they must be performed under slightly unfavorable circumstances. We might go still further, and take most extreme views and operate on every child born into the world. This plan would annihilate the disease; but it would be performing an operation, the necessity for which might never arise in the large majority of the cases. The writer, after studying all available statistics of recent origin, and comparing them with his own, has come to the conclusion that any case after thirty-six hours that is not improving in every way, should be operated upon at once, since Fowler has demonstrated that operation in forty-eight hours in 127 cases 83 per cent. recovered. When the cases were left to the fourth day there was 60 per cent. recoveries, to the fifth and sixth day, 58 per cent., to the seventh to the eighth day 50 per cent., and to the ninth to tenth day 33 per cent. The value of the early operation depending upon the condition of the patient in forty-eight hours after the onset of the attack is thus obvious. The results would be still better if the operation was performed within thirty-six hours. Now let us suppose the simple case is not operated upon at the end of thirty-six hours; but is left to recover without operation. If this type of case is now operated upon, say a month after the attack, the recoveries, debarring an accident, ought to be 100 per cent. This line of practice seems to yield the best results and is extremely radical under certain conditions and quite conservative under other conditions. This plan of allowing the simple catarrhal cases which are doing well after thirty-six hours to recover without immediate operation, and relegating them subsequently to the group known as interval cases, and the prompt operation after thirty-six hours when the cases are not doing well, seems to hold out the best prospects of recovery. The pendulum has swung too far toward indiscriminate operation, but now the introduction of the interval operation has brought the pendulum back to swing within the proper limits. There are some cases where the surgeon ought not to wait even thirty-six hours, but operate at once; it may be within twelve hours after the onset of the disease. These cases are rare; but they occasionally occur, and in this type of the disease no time must be lost to save the patient, since early operation is the only salvation. If a rule is laid down which applies to the surgeon to operate in all cases immediately, this rule would be inapplicable in country practice to the family physician. Morris states that "a surgical death rate of 2 per cent. is illegitimate in cases operated upon in the first attack before infection has extended beyond the confines of the appendix." Such a statement is misleading because there is bound to be, and there always will be a death rate in certain varieties of bacteria, no matter how soon the operation is performed. Bull has collected statistics in which he gives a death rate of about 2 per cent., but those cases are all interval cases collected from various sources. It is in this class of cases the writer believes that there should be no mortality at all, debarring an accident. Oschner has recently contributed some statistics from his own operations during one year, which reflect great credit upon his excellent work. In the acute cases there was a mortality of 3 per cent., and in the chronic cases there was a mortality of 1 per cent. In the entire number of cases, both acute and chronic, there was a mortality following the operation of 2 per cent. Deaver has also recently contributed some statistics from his own operation extending over a period of one year, which likewise reflect great credit upon his surgical skill. In the cases of general and diffuse peritonitis there was a mortality of 31 per cent. In the cases in which there was abscess there was a mortality of 12 per cent. In the cases in which the disease was confined to the appendix, with stricture, ulceration, and necrosis of the mucous membrane there was a mortality of 0.8 per cent., and finally in all the cases operated upon, the total mortality was 5 per cent. Richardson's published statistics are practically the same and the result of these various operators give an idea of what surgery has accomplished. In a study of the last 119 cases of appendicitis occurring in the practice of the writer up to April 1, 1903, the mortality of the disease, irrespective of operation or of any special plan of treatment, was a little over 1½ per cent. In the cases treated without operation, in which the attack was a mild catarrhal one, and in which the patients were not operated upon during the attack, the mortality was zero. In this group of cases in which conservatism was employed for special reasons, the appendix was in many cases subsequently removed owing to repeated attacks, and the mortality was zero. In the group of cases in which the appendix was gangrenous and had ruptured into the peritoneal cavity with a general purulent peritonitis, of which there were 11 cases, the mortality was zero. In the cases in which there was an acute perforative appendicitis, and in which the appendix was gangrenous, and found in a circumscribed abscess cavity, the mortality was 7 per cent. If now in this group all the operative cases are collected, both acute and chronic, the death-rate was 2 per cent. If the two fatal cases in the entire list of 119 cases are eliminated, which were hopeless from the start, but which were operated upon because it was offering the only possible chance of life, forlorn as the prospect was, the mortality of the disease was zero. The mortality of the operation both for acute and chronic appendicitis was also zero. Such cases as the two that died will always occur, and will always prevent the absence of mortality in the disease. In other words, if the two fatal cases are eliminated on the ground that surgery is powerless to save where complications, such as empye-

ma and abscess of the lung, exist, the mortality in the medical and operative treatment of this disease in 117 consecutive cases was zero. The two deaths, which make the mortality of the operation in all cases about 2 per cent., which in itself is insignificant when the nature of the disease is considered, deserve special consideration.

The first death was due to alcoholism and empyema and exhaustion in a tramp who was found by the police in the hallway of a tenement house upon a very cold night. He was brought to St. Vincent's Hospital in an exceedingly grave condition. The second death was due to an abscess of the lung consecutive to a subphrenic abscess caused by a suppurative appendicitis. In a study of these two cases of appendicitis it is evident that the special conditions in each case indicate that they belong to a class that no surgeon can save. The first case was operated upon to offer the man his only hope, and yet the conditions were such that practically precluded any prospect of success. The second case was hopeless, since the disease involved simultaneously other and vital organs. These two cases were fatal from the start, or, at least, fatal at the time when seen by the surgeon, and involved a general infection too widespread to expect any result from operative interference. When it is considered that in this list there were eleven cases of perforation with pus free in the peritoneal cavity and general peritonitis, all of which recovered, it is evident that modern surgery has advanced to such a point that little, if any improvement can be made in the treatment of this heretofore fatal disease. In other words, modern surgery has almost completely gained the mastery over the disease, since a mortality of about 2 per cent. can hardly be expected to be improved upon in the future.

Before discussing the operative cases, the writer desires to express his views in a most emphatic way in regard to operative interference in the catarrhal cases. These views especially refer to patients seen by a surgeon whose only claim to the title is the fact that he is licensed to practice. He may have no competent assistants, and the environment bad in the extreme. A patient under such circumstances is far safer in catarrhal appendicitis, to be treated by lavage of the stomach, the ice coil, the abstinence from food, except by the rectum, a plan suggested by Ochsner, than to be operated upon by a novice, whose experience in abdominal surgery is confined to the knowledge obtained from a text-book. The mortality of the simple operation is appalling in the hands of an inexperienced surgeon. The writer has knowledge of one surgeon who operated upon 19 consecutive cases with 19 deaths. After the attack is over, the appendix can be removed as an interval operation with safety if performed by a well-trained surgeon. The writer once saw a surgeon operate in which he attempted to tie the appendix off about midway between the tip and the base. A kindly remonstrance or timely suggestion in this case saved the patient's life without any doubt. If the plan of treatment suggested by Ochsner is not followed by marked relief within twenty-four hours, operation should be immediately performed. There is no doubt that as a rule to which exception can occasionally be found, and the simple catarrhal cases appear to be one of the exceptions, these cases recover without serious disturbance, and the appendicular colic subsides, while the appendix does not become seriously altered in its anatomical or pathological aspect, and the parts practically resume their normal condition. This class of cases must not be confounded with another class in which inflammation is present, and in which the process is likely to go on to suppuration. The absence of any improvement in thirty-six hours, and the exacerbation of all symptoms would relegate the simple catarrhal cases to a category requiring immediate operation. In the catarrhal cases the surgeon must not be induced to operate by a leucocytosis obtained by one single blood count. In one case of simple catarrhal appendicitis which the writer saw in a neighboring city, the blood count was 19,500, and every step was taken to operate as soon as preparations could be made. The patient was seen at midnight in a boarding school for young ladies, and the operation was to take place the next morning. A blood count was again taken, and instead of 19,500, the count was 9,000. All symptoms disappeared quickly, and the young girl was brought to New York, and after a few weeks the writer removed the appendix in the interval. The organ was slightly thickened and the lumen narrowed, but there was no evidence of there having been any pus or perforation at the time of the attack, when the blood count was so high. The blood count to be of any value must show a marked leucocytosis which constantly rises and continues high, since even in simple catarrhal appendicitis, a leucocytosis may be found which, however, is only temporary; but nevertheless misleading if a decision to operate is based upon the results of one single examination. Only recently the writer saw a patient with catarrhal appendicitis with a blood count of 16,000, the patient showed marked signs of improvement, and after recovery the appendix was removed as an interval case. The appendix was adherent to the intestine and omentum; but there was no evidence of any abscess. The single blood count in this case, as in the one just mentioned, was misleading as to the presence of suppuration. There is an inflammatory leucocytosis which must not be confounded with suppurative leucocytosis. The character of the leucocytes may throw some light upon the subject. There are two varieties of leucocytosis: one termed an absolute leucocytosis in which there is an increase in the total number of leucocytes, and a relative leucocytosis in which there is an excess of the normal percentage of the polymorphonuclear cells. Since the percentage of polymorphonuclear cells in the normal condition is about 70 to 75 per cent., an increase of 85 to 100 per cent. indicates some grave condition in which pus is present. The diminution in the absolute

leucocytosis is always a favorable sign, provided, however, there is no relative leucocytosis present. This fact must be always investigated in order to attach any value to the falling absolute leucocytosis. In other words, a falling absolute leucocytosis may portend good or evil, depending upon the percentage of the polymorphonuclear cells. It must be remembered also, that it is not always, though usually it is the case, that there should be an increase in the number of the leucocytes in order to have a leucocytosis even in inflammatory conditions. This clinical fact must be kept in mind since there may be no appreciable rise in the count, and yet the condition known as leucocytosis be present. It is the relative high percentage of the polymorphonuclear cells which establishes the presence of a relative leucocytosis just as the increase of the leucocytes gives rise to an absolute leucocytosis. In other words, it is not the increase in the number of white cells only that indicates a leucocytosis, since the proportion may be normal, or even sub-normal, and yet a leucocytosis be present, as is shown by the presence of the polymorphonuclear cells. This latter condition is often seen when the pus is walled off in a small circumscribed cavity. The presence of iodophilia is very strong evidence of the existence of pus. Leucocytosis may be absent in a mild catarrhal attack, also in small walled off cavity of pus and in the virulent form of infection, when the patient is too feeble to respond to the action of the toxemia. For the purpose of study these cases will be divided into three groups. In this way the mortality in each variety can be estimated. *First.* The appendectomies performed in the interval. *Second.* The acute perforative and gangrenous appendicitis with abscess. *Third.* The acute perforative appendicitis without a limiting abscess but with pus free in the peritoneal cavity, and with general peritonitis. (1) The appendectomies performed as interval cases all recovered without any complications. These cases can be set aside with the mild simple catarrhal cases without further discussion. (2) The cases of acute gangrenous appendicitis with perforation and abscess deserve special consideration. In this class there were 28 cases, and the mortality occurred in this variety and, strange to say in the 11 cases with perforation and pus free in the peritoneal cavity, no death occurred. It is difficult to understand why the mortality was present in these cases and absent in the cases of general peritonitis. The virulence of the infection offers the only explanation, and in this class of cases surgery has been and probably always will be powerless to avert the fatal issue. (3) The acute perforative appendicitis without a limiting abscess, but with pus free in the peritoneal cavity, and with general peritonitis.

The 11 cases of perforative and gangrenous appendicitis with general peritonitis form a unique group by themselves. Every one recovered, and no case has been omitted that occurred within the limit of time designated. It is in this class of cases that the real triumph for modern surgery is demonstrated. It is expected in these days that all chronic cases will recover after interval operations. It is also expected that nearly all cases of perforative and gangrenous appendicitis with limiting abscess will recover. It is not expected that cases of general peritonitis will recover. These are the cases that are so fatal, and that contribute to the mortality of the operation. These 11 cases in the general list deserve special consideration, because they teach that modern surgery can still offer a chance of life in cases, where, until recently, death was an inevitable result. A brief report of the 11 cases will reveal the conditions present in each individual, the operative measures instituted for relief in each patient, and the final result in each case, not as regards life, since they all recovered, but as regards the after treatment, as it pertains to the repair of the wound, the absence of hernial protrusion, the disappearance of sepsis, the restoration of the function of the alimentary canal, and the improvement in the general health following so grave an operation performed for the relief of a condition which, until recently, was uniformly fatal. The writer will append an abstract of the 11 cases in which general peritonitis was present in order that an idea may be obtained as to the serious character of the cases in this group.

Case I.—Gangrene and perforation of the appendix with general peritonitis. Operation. Recovery. J. M., æt. eleven years, was admitted to St. Vincent's Hospital suffering from acute appendicitis. Five days before admission patient was taken ill with violent cramps in the abdomen, and frequent attacks of vomiting. The bowels were constipated, but the day previous to his entrance into the hospital had moved once after a cathartic administered by the family physician. Upon admission patient was very anemic and poorly nourished. His face was pinched, haggard and careworn; the eyes were sunken and hollow; the body extremely emaciated; the tongue badly coated; the pulse was 100 and feeble; the temperature was 102° F., and the respirations were 26. The abdomen was very tympanitic and exquisitely tender to the slightest touch; the pain was very severe and diffuse, extending all over the abdominal cavity. No tumor was palpable, either externally or by rectal examination. The vomiting was persistent and at one time as much as six ounces of dark brown fluid was ejected. Upon examination of the patient the same evening of his admittance the writer decided to open the abdomen as the general tenderness and tympanites and distention were so severe that it was evident delay would not be advisable. The vomiting too, pointed to some grave lesion of the appendix, and his general condition made it necessary to interfere without delay.

Every preparation for an antiseptic operation was made, and after the administration of a small quantity of ether, laparotomy was performed. The usual incision was made and the peritoneal cavity opened. A very fetid, purulent, brown fluid flowed out in abundance from the general peritoneal cavity. The appendix was black, gangrenous

and perforated, and lying upon the anterior surface of the cecum, which was also black and gangrenous. Pus flowed freely out of the opening in the peritoneum, beneath which the coils of the intestine could be seen covered with a purulent exudation. The wound was now enlarged and some of the coils of intestine toward the median line were found to be adherent to each other. In other words, there was no abscess cavity, no limiting membrane shutting off the pus, which was free in the general peritoneal cavity.

The question as to the immediate treatment of the gangrenous parts was not considered. Obviously the cecum was destroyed, and any resection with approximation, under the existing local and general conditions, was impracticable. Conservative treatment of the wound offered to the little patient the safest course, and, accordingly, the parts were left as undisturbed as possible, in the hope that nature would come to the rescue.

The appendix was ligated and removed, and the wound left open for drainage and disinfection. The wound was still further enlarged in order to permit of irrigation. Hot bichloride of mercury of the strength of 1-2,000 was first used, and after the visible pus was washed out, a solution of peroxide of hydrogen was slowly and gently injected into the cavity, and this irrigation was quickly followed by a free ablution of the peritoneal cavity by hot saline solution. The wound having been thoroughly disinfected and drained, an antiseptic dressing was applied.

At the end of the third day a complete cast of the cecum came away, together with gas and feces. The slough was subjected to microscopic examination, and it was reported to be only the peritoneal coat of the cecum, and that the slough had invaded only the outer wall of the intestine except at one point, where the rupture occurred. On the seventh day another large slough was discharged, and then the wound began to show signs of repair, as the granulations were beginning to appear healthy. On the fourteenth day still another slough came away while gas and feces continued to be discharged. Upon the outer surface of the cecum bright red sensitive granulations sprang up and gradually filled up the space, covered in the cavity and closed the fistula.

Remarks.—In this case, as the result shows, nature will do miraculous things, if only the surgeon does not interfere. Any unnecessary handling of the parts beyond that which is absolutely necessary to permit the free disinfection and drainage, the breaking up of distant adhesions, the handling of the infected portions of the intestines, the breaking down of nature's barriers, the interference to bring about an anastomosis when the parts are gangrenous and ruptured, all tend to jeopardize the patient's life; whereas disinfection, drainage, a medium of interference sufficient to meet the requirements offer to the patient the best chance of life. The complete repair of the wound, the entire closure of the fistula, the reestablishment of the continuity of the bowel, all were brought about by simply aiding nature in her reparative work; without doubt any other course would have caused the death of the patient.

Case II.—Perforative appendicitis with general peritonitis. Operation. Recovery. B. C., æt. twenty-three years, was admitted to St. Vincent's Hospital suffering from a severe attack of appendicitis. Four days previous to admission to hospital patient was taken ill with violent pains in the abdomen accompanied by nausea. Upon admission to the hospital, at 7:30 P.M., her temperature was 102.4° F., pulse 100, and respirations 28. Her tongue was coated, great thirst was present, and the kidneys secreting but little urine. Upon examination, the abdomen was very tender and distended, especially in the right iliac region. An ice coil was applied; strychnine and nitroglycerin were administered at intervals during the night; the bowels moved as a result of an enema and the patient vomited only once, although nauseated. The writer saw the patient upon the following morning and found the temperature 99° F. The pulse 100 and respirations 22. The abdomen was more tender and the tympanitis increased. Owing to the rigidity of the abdomen, the general tenderness, the presence of nausea and vomiting the writer decided to operate. Upon reaching the peritoneum very fetid pus gushed out from the opening and the intestines were extremely congested and were covered with pus, lymph and a fibrinous exudation. There was no abscess cavity, no limiting membrane, no special adhesions shutting off any circumscribed area. Pus was free in the cavity and surrounded and covered the intestine. The appendix was not found in this case. This part of the peritoneal cavity was now walled off by gauze and an attempt was made to thoroughly irrigate the infected area with hot bichloride solution, peroxide of hydrogen and finally with sterilized water. When this part of the cavity was thoroughly cleansed the mops were removed and the adjacent intestines were washed with the same solutions, and the general cavity washed out with a hot saline solution. The wound was now drained, and the patient made a slow, but otherwise satisfactory, recovery.

Remarks.—This case shows very clearly that the condition of the pulse and temperature fails to offer a reliable guide as to the exact condition of the patient. A temperature of 99° F., is not expected in a gangrenous appendix with pus free in the cavity. Yet in this case the temperature failed to reveal the real pathological condition. The case is interesting too, in the fact that notwithstanding the presence of a large opening into the peritoneal cavity for several weeks, the abdominal wound closed.

Case III.—Acute perforative appendicitis, with general septic peritonitis. Operation. Recovery. M. McG., æt. eleven years, was admitted to St. Vincent's Hospital suffering from acute appendicitis. Three days previous to her admission patient was taken ill with severe abdominal pains, nausea and vomiting. At the onset of the attack the pain was general over the abdomen, but later became

localized in the right iliac region. Upon examination, immediately after admission to the hospital the abdomen was found very distended, tympanitic and rigid, and also very sensitive to the touch. The temperature was 103.8° F., pulse 120, respirations 30. Having taken every antiseptic precaution and having placed the patient under the influence of ether, the abdomen was opened. Fetid pus flowed out of the opening into the peritoneal cavity and the intestines were congested, and covered with a fibrinous exudation and pus. There was no abscess cavity, no walling off of the infected area by adhesions, in fact, there was nothing that prevented the free access of pus into the general peritoneal cavity. The most infected area was now walled off with pads of sterile gauze and this infected area thoroughly irrigated with hot bichloride, then peroxide of hydrogen, and, finally, by hot saline solution in large quantities. The mops were removed and the same process repeated in the general cavity, and the wound was then left open for the purpose of drainage. Patient made an uneventful recovery, and suffered only as one would recovering from so serious a disease. The wound granulated and was entirely closed in, and the resulting cicatrix was firm, leaving no weakness in the abdominal wall.

Remarks.—In this case, as in the preceding one, the opening of the abdomen, the free irrigation of the localized area at first, and then the general irrigation, the provision for drainage offered the best chance for recovery. The appendices in these two cases could not be found as they had evidently sloughed and were in the débris forming the purulent collection. Only a limited search for the appendix was made in this case, since it is the meddlesome interference that causes death in these cases.

Case IV.—Acute perforative appendicitis with general septic peritonitis. Operation. Recovery. J. B., æt. twenty-six years, was admitted to St. Vincent's Hospital suffering from acute appendicitis. The day previous to his admission he was taken suddenly ill with abdominal cramps, which he states were general. He vomited once only before coming to the hospital. He stated also that he had suffered from two previous attacks of like nature, one occurred a month before his present attack, and the other about two weeks before. Upon his admission to the hospital his temperature was 99.8° F., his pulse 72 and of good character, and his respirations 18. His tongue was coated, his urine was diminished in quantity, his bowels were constipated and great thirst was present. Upon examination the abdomen was slightly tympanitic and tender to the touch, and his right rectus muscle slightly rigid. The absence of vomiting and severe pain, the presence of practically normal temperature and pulse, and his general satisfactory condition, taking into consideration the very mild character of his two previous attacks, seemed to justify noninterference, at least for the present. As the writer had made arrangements to be out of the city the following day to remove an appendix, he left instructions with the house surgeon to have Dr. Bissell, the assistant surgeon, see the case for him, and in the event of any change, to operate at once. During the following thirty-six hours a marked change occurred. The patient began to vomit, his temperature rose to 102.6° F., his pulse, however, rose only to 84 and his respirations 26. The tympanitis was increased and great tenderness was present over the abdomen. The patient became very restless and there was evidence of very serious disturbance about the appendix. Notwithstanding the decline of two degrees of temperature the pulse increased to 106, and the general condition called for interference. Dr. Bissell operated at once, and to him is due the credit for the recovery of this patient in my service. The abdomen was opened under every antiseptic precaution and the fetid pus flowed freely from the opening in the peritoneum. The appendix could not be found, and the cecum was black and covered with fibrinous exudation. Pus was free in the cavity and no adhesions had taken place to wall off the infected area from the general peritoneal cavity. The peritoneum was inflamed, and pus surrounded the coils of intestine. The immediate infected area was subject to irrigation in the manner already described, and then the patient was rolled upon his right side, and free irrigation was employed in the general peritoneal cavity, and the wound drained. Upon the second day following the operation the appendix came away while irrigating the wound, and the patient made an uneventful recovery. The wound healed and no fistula or hernia resulted from the operation.

Remarks.—The bacteriological examination showed that *Streptococcus* was the germ of infection in this case and not the *Bacillus coli communis.* From a clinical point of view this has much of interest attached to it. It illustrates the necessity of immediate and early operation in those cases where there have been repeated attacks. This seems to be true even in the face of practically a normal temperature, normal pulse respirations, and absence of vomiting. To be sure certain primary cases rapidly change for the better after the third day, but in the cases where the attacks are multiple, the operation is more likely to be successful if performed at once, than if left until conditions are more serious. This case also shows how unreliable are pulse and temperature as indicating the severity and danger of the disease.

Case V.—Acute perforative appendicitis with gangrene and rupture of the appendix. General peritonitis. Operation. Recovery. I. M., æt. ten years, while in perfect health was suddenly attacked with violent pains in the abdomen accompanied by vomiting, and serious constitutional disturbances. Upon the third day of his illness, the writer was asked to see the patient by Dr. Dalrymple, of New Rochelle. Upon examination, he found the patient suffering from serious constitutional disturbances. The pulse was 120, and the temperature nearly 104° F. The abdomen was greatly distended, rigid and tym-

panitic. The boy was in great pain and the writer advised an immediate operation, to which the mother consented. The peritoneal cavity was opened and a large quantity of fetid pus flowed out through the opening. The intestine was covered with pus and lymph, and the peritoneum intensely inflamed. There were no firm adhesions of the intestines to one another, and no circumscribed abscess wall. Pus was free in the iliac region, and the appendix was found gangrenous, with a perforation. The appendix was now ligated in the usual manner. The iliac cavity was walled off with pads of gauze, and the pus and inflammatory exudates washed out with a solution of bichloride of mercury, and then with peroxide of hydrogen and hot saline solution. After the part of the peritoneal cavity in which the appendix was situated was thoroughly disinfected, the general cavity was irrigated by using the same disinfectants, with the boy turned upon his right side. The wound was now drained and partially closed.

Remarks.—This case, with the preceding four, illustrates the value of an operation with gangrenous appendix and rupture, and suppurative peritonitis. Emphasis is placed upon the treatment of local disinfection of the iliac region and then the general disinfection of the peritoneal cavity. With the exception of great difficulty in getting the bowels to move after the operation, he made an uneventful convalescence. The cicatrix is firm, and there is no weakness in the abdominal wall at this point in consequence of leaving the wound open for drainage. This makes the fifth consecutive case of perforative appendix with suppurative peritonitis occurring within a few weeks, and offers encouragement to operate in those cases where the conditions are such as to lead one to expect a quick and fatal termination.

Case VI.—Acute perforative and gangrenous appendicitis with general peritonitis. Enterolith found in peritoneal cavity. Operation. Recovery. J. T., æt. fourteen years, was admitted to St. Vincent's Hospital suffering from acute appendicitis. The patient was treated outside for several days, and was brought to the hospital *in extremis*. The temperature was elevated, the pulse was accelerated and the respirations were rapid. As the condition was serious, an immediate operation was deemed necessary. The abdomen was opened, and a peritonitis was found, and the appendix was perforated by a fecal calculus about the size of a pea. The concretion was found in the search for the appendix, and was lying free in the cavity of the peritoneum, which was the seat of an acute peritonitis. The appendix was removed, the peritoneal cavity was irrigated after first disinfecting locally the region of the ileocecal valve, and then the general cavity drained and the wound partially closed. The patient made an uneventful recovery.

Case VII.—Acute perforative and gangrenous appendicitis. Pus in peritoneal cavity. General peritonitis. Operation. Recovery. J. B., æt. twelve years, was admitted to St. Vincent's Hospital suffering from severe abdominal pain. The boy was at school the day preceding his admission to the hospital, and twenty-four hours previous to his admission to the hospital he was apparently well. The attack began with violent pain, vomiting and rise of temperature. He attended school the morning previous to his entrance to the children's ward. The attack was thus very sudden in its onset, very severe in its character, and denoted a most virulent and rapid infection, calling for an immediate operation. Upon examination his pulse was found to be 140 to 150, respirations 40 per minute, and his temperature 104° F. He had been vomiting for the past twelve hours, suffered great pain over the appendix, had a rigid abdominal wall, and severe colicky pains in the right iliac region, with great tenderness over the appendix. A blood count was made, and there was a leucocytosis of 20,000. An operation was performed at once, and the appendix was found perforated and gangrenous, and pus was free in the peritoneal cavity. The peritoneal cavity was drained, and the patient made an entirely satisfactory recovery.

Case VIII.—Gangrene and perforation of the appendix with general peritonitis. Operation. Recovery. W. H. was admitted to St. Vincent's Hospital with a temperature of 103° F., pulse 128, and respirations 38. The patient complained of great pain in his right iliac region, which had come on suddenly with an attack of vomiting. Pain was very severe over the region of the appendix. In view of the alarming symptoms, the patient was placed at once under the influence of an anesthetic, and an operation was performed on the same day of his admittance to the Hospital. The appendix was found gangrenous and perforated, without any abscess cavity. Pus was found in the right iliac region, as well as in the peritoneal cavity. The appendix was ligated, and the stump touched with a strong solution of carbolic acid. The right iliac region as well as the peritoneal cavity were washed out with a solution of bichloride of mercury of 1 to 4,000, after that with a hot saline solution. A rubber drainage tube wrapped with sterile gauze, over which rubber protective was wrapped, was introduced into the right iliac fossa, down to the stump of the appendix. An incision was made upon the back where the cavity was drained in the same manner. Drains were also introduced near the median line in the general peritoneal cavity. The patient's temperature fell in forty-eight hours to 98.5° F., and ranged between that and 101° F. for several days. The temperature then rose again, and the abdomen was opened upon the left side, and a new pocket of pus was discovered. This was drained in the same manner as already described, and after several weeks all the openings were closed, and the patient made an uninterrupted recovery. The blood count in this case showed only 7,000 white blood cells at the time of the operation. The pa-

tient for many days was stimulated with whisky, sulphate of strychnia and nitroglycerin.

Case IX.—Perforative appendicitis with general peritonitis. Operation. Recovery. M. G., æt. eleven years, was admitted to St. Vincent's Hospital suffering from an attack of severe pain in the right side accompanied by nausea and vomiting. Upon examination there was found a rigid and distended abdomen, high temperature and rapid pulse with considerable shock. The blood count showed a leucocytosis of 17,000. The abdomen was opened and pus was found with a gangrenous appendix. The abscess was not walled off in every direction, and pus had escaped previous to the operation into the general peritoneal cavity. The abscess cavity was mopped out and made as sterile as possible and the general abdominal cavity thoroughly washed out with peroxide of hydrogen, then bichloride of mercury, and, finally, with hot saline solution. The appendix itself was found which was tied off and a tube wrapped round with sterile gauze and covered by rubber tissue was inserted down in the pelvis to the stump. Free drainage was also provided for the general peritoneal cavity by means of sterile gauze wrapped in rubber tissue to prevent adhesions of the intestine. The patient recovered with a small sinus leading down toward the stump; but after a few weeks from the time of the operation, the sinus closed and the boy was discharged cured. In this case there occurred a clinical fact worthy of mention. The blood count to which mention has already been made showed the day following the operation a rise to 40,000, which gradually fell to normal. It was a strange coincidence that with a blood count of 17,000 upon the day of the operation the leucocytosis should jump up the day following the operation to 40,000. This is in marked contrast to the case of general peritonitis from rupture of the appendix in which the blood count was only 7,000 with pus free in the general peritoneal cavity.

The tenth and eleventh cases of acute perforative gangrenous appendicitis with general peritonitis present nothing unusual in their histories. Suffice to say that these cases were operated upon in the same manner as has already been described and drained in the same way, and both recovered without hernia. This makes 11 consecutive cases of acute perforative and gangrenous appendicitis with general peritonitis with recovery; there is certainly nothing more to be learned in the management of these hitherto almost uniformly fatal cases. Surgery has accomplished by slow advances, and by repeated elimination, a method of cure for these cases, and can point with pride to its success in saving lives that formerly were lost by indecision to operate, and faulty technic.

The question of the reduction of the mortality in appendicitis confronts the family physician as well as the practical surgeon. On the family physician the writer would impress the clinical fact that appendicitis is essentially a surgical affection, and is governed by all the laws that pertain to acute infective inflammations in other parts of the body. If the case is not pursuing a favorable course after thirty-six hours of recognized medical treatment, it should be relegated to the domain of surgery. If the case is doing well within the limit of time mentioned, delay is possible as far as immediate operative interference is concerned; but still the case should be referred to a surgeon with a view to an interval operation. It would be a sad calamity for a patient to succumb to a fatal recurrent attack for want of having had an opportunity offered him to prevent his or her death. If the opportunity has been offered and the patient declined the operation, the responsibility rests with him, or with her, and the family physician is relieved of that responsibility. On the practical surgeon the writer would impress the clinical fact that early operations are almost always successful, and late operations are attended by a certain mortality. The ideal plan is to operate after thirty-six hours if the symptoms are serious, with a view to the reduction of the present small mortality. Besides the duty which belongs to the family physician, and the duty which devolves upon the practical surgeon, there is still a common, reciprocal duty that belongs to both. The mortality in appendicitis can only be reduced by a hearty, cordial cooperation of both physician and surgeon, and when these relations are established, the death rate, small as it is, will be still further reduced, and both the physician and surgeon can, by united action, contribute to the comfort and salvation of the patient. It is in this way only that the death rate can be reduced, and until the family physician and the practical surgeon meet on a common ground, and consult in perfect harmony, the death rate will remain where it is. On the other hand, with the establishment of more cordial and intimate relations between these two representative members of the profession, the small death rate in this disease will be still further reduced and both the physician and the surgeon will equally contribute to the one grand object, the saving of human life, than which no other calling or duty is more grand or noble in the history of the race.

THE RELATION OF PROTEIDS TO EDEMA IN MARANTIC CHILDREN; WITH URINALYSES IN INFANTILE DIARRHEA.*

BY PALMER A. POTTER, B.S., M.D.,

OF EAST ORANGE, N. J.;

MEMBER ALUMNI SOCIETY, NEW YORK CITY HOSPITAL, ALUMNI NURSERY AND CHILD'S HOSPITAL., MEMBER ESSEX COUNTY MEDICAL SOCIETY.

In an article entitled "A Study of 555 Cases of Summer Diarrhea," by C. G. Kerley, read before the American Pediatric Society in 1901 and published in the *Archives of Pediatrics*, the statement is made that brandy and whisky should not

* Read before the meeting of the Alumni Society of the New York City Hospital, October 14, 1903.

be used as stimulants because of the frequent involvement of the kidney in diarrheas of that character, and the consequent danger of provoking that common complication by the use of alcohol. At the time the paper was read there seemed to be a difference of opinion as to whether the kidneys were involved; and to settle this point to his own satisfaction, as far as is possible clinically, the writer, while House Physician at the Nursery and Child's Hospital, examined the urine of a number of children with acute fermentative or infectious diarrheas.

Cases were chosen for examination that came under one of the four following heads—and then only when the urine could be collected during the height of the attack: (1) Cases with marked diarrhea, high temperature, great prostration and blood or mucus in the stools. (2) Cases in whose stools the *Bacillus dysenteriæ Shiga* was found. (3) Cases whose blood serum agglutinated the Shiga bacillus—this test rests upon the authority of Dr. W. H. Park, of the New York Board of Health. (4) Cases marked by edema of some part of the body, with or without the presence of a marked acute diarrhea.

The idea in taking the acute cases was to avoid mistaking degenerative changes in the kidney, consequent upon the long wasting illness, for acute inflammatory processes due to the diarrhea itself. The second and third classes, viz., those in whose stools was found the Shiga bacillus or whose blood serum agglutinated those bacilli, were chosen because the specific infectious nature of the disease was considered proved and not purely dependent upon errors of diet. Although Dr. Joseph Winters, in the *Medical Record*, of March 7, 1903, considers the original bacterial influence as nil and errors of diet the entire cause, both predisposing and exciting, in all cases of infantile diarrhea. Special emphasis is laid upon the cases marked by edema, most of them occurring during an attack of diarrhea, because of the comparative rarity of this condition, the different theories of its etiology, and the absence of any regular and previously efficacious treatment.

In the first class of cases the results of but twelve urine examinations are given. The number is limited because the cases were confined strictly to the very severe ones—those with intestinal toxemia—and because of the difficulty of collecting the specimen, particularly in the female babies, before the usual treatment improved the condition. When the urine could not be collected until the condition had improved the case was not included in the list.

Of those 12 cases but one, Willie F., eight months old, showed any albumin in the urine and then only a slight trace. The child had a diarrhea for two days and at the time the specimen was obtained had a temperature of 104.4° F. Indican was found in the urine of but two.

Hyaline casts were found in two other specimens, both children being under four months old, at which age, little, if any, significance, can be attached to their presence.

In the second and third classes, in which the specific bacterial origin of the disease is considered settled, were four cases. The blood serum of two of these agglutinated the Shiga bacillus, taken from a pure culture, and in the other two the bacillus was found in the stools. The latter fact rests upon the authority of Dr. Steele of New Haven. In none of these cases of proved specific infection was any trace of albumin, or other evidence of inflammatory kidney process found.

The cases with edema are taken up in detail because this condition is rarely met with, and when it is, is usually ascribed to cardiac or renal disease, although apparently independent of either. The writer is able to find it mentioned in but one of the standard text books of pediatrics.

As dropsy in the legs frequently accompanies heart lesions, and in other parts of the body accompanies heart or kidney lesions, the presence of edema in infants naturally leads to the belief that one of these organs involved. Clinical evidence, however, would appear to show that this is not necessarily the case.

Edema in marantic infants during an attack of diarrhea, differs from the dropsy often seen toward the end of a long, wasting illness, such as pulmonary tuberculosis or carcinoma, in that it is not necessarily an ante-mortem sign. Of the six cases mentioned in this paper, five recovered. The individual cases were as follows:

Case I.—Six months old, weight 6½ pounds, vomiting, refusal of food, fever, frequent defecations of curds and mucus. Temperature 104° F. Barley water was substituted for milk and the usual medical treatment instituted. In next twenty-four hours the edema began in soles of feet, a slight reddening of the skin being the first thing noticed. In twenty-four hours the eyelids were puffy, in the next twenty-four the whole face became so swollen that the eyes could not be opened and the legs were also much swollen, with deep pitting on pressure over the tibia. While impossible to collect the total urine for measurement it appeared to be slightly less than usual. The results of the examination of the specimens collected were negative, the sp. gr. being 1.014, with no casts, no albumin, no indican. The hemoglobin was 70 per cent., the leucocytes 8,500 and the clotting of the blood apparently normal.

During the increase of the edema the regular treatment, dietetic and medical, for the preexisting diarrhea, was carried out. At the same time systematic treatment for the edema was instituted, as recommended in the only text book containing any information on the subject. Heat over the kidneys, diuretics, as spiritis etheris nitrosi, citrate of potash and fl. extract of digitalis, were all used, but with no decrease in the edema, nor improvement in the general condition. Finally all medication was stopped. The food, which during the worst part of the diarrhea, had been plain barley water and which now contained by the addition of 4 per cent. milk, .75 per

cent. of fats and proteids, was abruptly changed to a mixture containing 2½ per cent. of proteids and fats and in sixteen hours the edema had entirely disappeared. The general condition improved from that time, and continued to do so, although the food had to be carefully regulated.

Case II.—Age ten months, weight 8 pounds. This was a typical marasmus case, as will be seen from the age and weight. Brought in for bad, frequent bowel movements. On first examination soles of feet were slightly swollen. Twelve hours after admission eyes were puffed up and the child gained seven ounces in two and a half days. The regular, generally acknowledged treatment for the existing diarrhea would have been withdrawal of all milk, to avoid forming new culture grounds for the bacteria. The presence of the general edema was so ominous, however, and the child's general condition so bad, that, from the lesson of the previous case, the amount of proteids in the food was rapidly increased, with entire subsidence of the dropsy and a loss of 10 ounces in weight. The general condition rapidly improved under the increased proteids, although the stools continued somewhat frequent and curdy. The urine in this case during the height of the edema was voided but once in sixteen hours, and showed no indican, but did have a slight trace of albumin and a few hyaline casts. The hemoglobin was about 45 per cent. and coagulation apparently not retarded, leucocytes about 10,000, the proportions of the various kinds being about as usual.

Case III.—Ernest H., aged ten months, weight 9 pounds 8 ounces. This case had been in the hospital for several weeks with malnutrition, when the edema began. He was being fed on a mixture of 4 per cent. milk and barley water, in which the fats and proteids approximated 1½ per cent., the sugars six. On Sept. 27, his eyelids and feet began to swell, he gained rapidly in weight and many casein curds appeared in the movements, although the bowels continued regular. The proteids were lowered to one per cent., then raised to two per cent., and the milk peptonized. The edema disappeared and 11 ounces were lost in twenty-four hours. The urine and blood examinations were absolutely negative, the hemoglobin being 65 per cent. At the time of writing this child weighs sixteen pounds and is perfectly normal and healthy.

Case IV.—Stella S., aged three months, weight 7½ pounds. Was being fed on a mixture of 4 per cent. milk and Imp. Granum, 1½ oz. of milk to 3 oz. of Imp. Granum, a mixture in which the fats and proteids approximated 1⅓ per cent., the carbohydrates being high. On Oct. 17, almost a month after the appearance of any other case of edema, the temperature fell to 96° F., feet and then eyelids began to swell and six ounces were gained inside of twenty-four hours. Food was changed to a milk and whey mixture and the proteids increased to 2 per cent., then to 2½ per cent. and edema disappeared entirely in thirty-one hours. The bowels were disturbed in consequence of the increased strength of the food, but as the general condition improved and temperature rose to normal the formula was retained for one week. The urine in this case showed no albumin, no indican, a few hyaline casts, and there was no suppression. This child died seventeen days later of laryngeal diphtheria, twelve hours after intubation.

Case V.—Annie H., aged ten months, weight eight pounds eight ounces. Edema began on October 25 (during an attack of diarrhea) and progressed as in the other cases. The child voided urine but once in the first thirty-six hours after the edema began, and averaged in the next five days during which the edema lasted only four ounces in twenty-four hours. To contrast results the previously accepted treatment was adopted. Diuretics were given as in Case I, as well as the usual dietetic treatment for diarrhea, but edema persisted, although the condition of the bowels improved. On October 29, after dropsy had lasted four days, this treatment was abandoned and a milk and whey mixture given, and the fats and proteids rapidly increased to about 2 per cent., in addition to the lactalbumen in the whey. In thirty-one hours the edema had entirely disappeared and the general condition improved rapidly. The urine examination was negative in this case, as was the blood, the hemoglobin being 60 per cent.

Case VI.—Aged 3½ months, weight 6 pounds 2 ounces. A case of marasmus. Was put on a milk-whey mixture after coming in the hospital. On November 6, 1902, bowels became bad, and child was fed on plain whey. On November 17 edema began in the feet and progressed in the usual way but very rapidly, until the entire body, with the exception of the serous cavities, was much swollen. Urination apparently about as usual in frequency and amount. Weight increased eight ounces in three days. The bowels remaining bad, the child was still fed on whey, but two days after the onset of the edema, because of its rapid spread and in spite of the condition of the bowels, milk was added and rapidly increased with every feeding, until the proteids reached 2 per cent. plus the proteids of the whey. The edema decreased almost immediately and had entirely disappeared in two days. The urine showed no casts, and no albumin. The leucocytes were about 12,000 and the hemoglobin less than 40 per cent.

Case VII.—An Italian child, 4½ months old. Weight 4½ pounds. In this case diarrhea had existed five days before admission. The child had been fed on Russian tea and brandy and was in very bad shape. Within twelve hours after admission began to show edema. A combination of milk and whey, with the milk rapidly increased, was given, but not retained. After plain whey for six hours, during which the edema increased, small, repeated doses of milk and whey were finally retained. The edema entirely disappeared in 2½ days under increased strength of the formula. The urine was entirely negative, not even

hyaline casts being found. The polymorphonuclears outnumbered the lymphocytes. The hemoglobin was 50 per cent. The edema did not return and the child went out eighteen days later with a gain of eleven ounces and conditions much improved.

The heart sounds in all these cases were perfectly normal. Several theories have been advanced as to the cause of edema of this description. Dr. L. Emmett Holt thinks it due to the hydremia of the blood in the cases he has observed. Remlingen, in the *Revue de Médecine* of October, 1901, speaking of a few cases of edema without albuminuria observed in adults after severe or protracted attacks of diarrhea, ascribes the same cause. Dr. Rowland G. Freeman, from the cases observed at the Nursery and Child's Hospital, and at the New York Foundling Asylum, thinks it is of infectious origin. De Wolf, of Providence (*Archives of Pediatrics*, Dec., 1902) in describing an apparent epidemic of edema accompanying diarrhea in infants, considers it of renal origin dependent upon infection, presumably through the milk.

Of the cases here noted but two seemed to have any etiological relation. Cases II and III showed edema on the same day and were in adjoining beds in the same wards. All the others showed the condition at widely different periods and locations. The cases showing edema on admission to the hospital, entered after it had appeared in children already there, so could not have brought in the infection from the outside. As to the possible nephritic origin without albuminuria or other clinical evidence, the necropsy records for the past several years of Dr. Vanderpoel Adriance, pathologist of the Nursery and Child's Hospital, show that none of the cases with edema had any kidney lesions. L. Emmett Holt, in 70 autopsies on gastro-intestinal cases found but one affected kidney.

Dr. C. A. Herter—whom the writer is unable to quote verbatim, but from memory only—thinks the edema due to involvement of the sympathetic nervous system from severe constitutional depression. This view is certainly supported in the cases here presented by the improvement in the edema and also in the general condition, under an increase in the proteids in the diet. The usual dietetic treatment for diarrhea is of course the withdrawal of the proteid element in the food, but in cases marked by edema in mirantic children the constitutional resistance appears to be so slight that the proteids need to be retained and even increased, notwithstanding the locally irritant effect on the intestines. It appears to be a choice between aiding the general system and making the diarrhea worse—or rather not treating it after the generally accepted method—and improving the diarrhea with probably fatal consequences.

The recovery of the seven cases with the supposedly ante-mortem sign seems to warrant this statement.

To sum up: (1) Acute diarrheas—not protracted cases—are not accompanied by kidney involvement; (2) alcohol is not, therefore, injurious in this condition, if necessary for use as a stimulant; (3) edema during a diarrhea in mirantic infants is a bad sign, is not necessarily ante-mortem, is not due to the heart or kidneys and (4) the bad general condition is best treated by disregarding the diarrhea and increasing the strength of the proteids.

The writer is indebted to Dr. A. M. Thomas and Dr. R. G. Freeman for the privilege of making these investigations and of publishing the results.

DIAGNOSIS OF GALL-BLADDER DISEASES.

BY J. THOMPSON SCHELL, M.D.,
OF PHILADELPHIA;
OBSTETRICIAN AND GYNECOLOGIST TO PRINCE OF PEACE HOSPITAL, ETC.

THE diagnosis of cholecystitis, cholelithiasis, and cholangitis depends first, on the location of the inflammation or stone; second, on the degree and character of the inflammation, and third, to some extent on the size of the stone. The symptoms of these conditions vary from the well-known clinical picture of the so-called acute catarrhal jaundice to the obscure and indefinite symptoms of a chronic inflammation of the gall-bladder, which at times produce no symptoms at all.

To assert that the general diagnosis of cholecystitis and cholelithiasis is easy, and that the position of the calculus may in all instances be definitely determined is an acknowledgement of an unfamiliarity with the manifold intra-abdominal pathological lesions, which often present common and confusing symptoms.

The diagnosis of acute catarrhal jaundice offers probably as little difficulty as any of these conditions. A history of errors in diet, of a previously existing gastro-intestinal catarrh, age, young adult life, the appearance of jaundice and clay-colored stools, unaccompanied by pain or general emaciation, with little or no fever, urine containing bile pigment, and a slow pulse, form together a characteristic clinical picture, especially when there are no symptoms pointing to acute yellow atrophy, carcinoma or cirrhosis of the liver. When this condition develops in a patient, after the thirtieth year, we have a more difficult problem, as the above symptoms may mask a cholelithiasis, and pain similar to gall-stone colic can be caused by the expulsion of plugs of inflammatory mucus, closely simulating the passage of a gall-stone. A careful examination of the washed stools should be made, as some information may be gained in this way, although Naunyn has shown that gall-stones may be decomposed in the intestines. Chronic catarrhal cholangitis occurs in obstruction of the common duct, usually by gall-stones, less commonly by malignant diseases, strictures or by pressure on the outside. Osler recognizes two groups: (*a*) *Complete obstruction* of the common duct presenting chronic and intense jaundice without fever, a history of

previous attacks of colic, no, or very slight, enlargement of the gall-bladder; (*b*) incomplete obstruction of common duct when due to gall-stones presents recurrent paroxysms of pain, accompanied by chills, fever and sweats—the "Charcot hepatic fever." Jaundice is a variable symptom sometimes marked, other times slight. There is no enlargement of liver or gall-bladder and the health is not much affected. The condition is probably due to a repeated infection, not severe enough to cause suppuration. The blood must be examined in order to eliminate malarial fever, and if a tumor *is* present must have some other condition than obstruction of the common duct to account for it; either a growth, or an obstruction of the cystic duct.

Catarrhal cholangitis may extend into the minutest gall-ducts of the liver, and become persistent. The extrahepatic ducts then show little or no alterations. The important symptoms of this condition being a continuous jaundice and the course of the affection is that of hypertrophic cirrhosis.

Suppurative cholangitis usually follows immediately upon an attack of catarrhal inflammation or gives a history of such an attack. It is usually associated with gall-stones either in the ducts or gall-bladder, but not necessarily so. The symptoms are chills and fever of the remittent type, with grave constitutional symptoms indicating a septic pyemia, locally enlargement of the liver (in a badly infected case), colicky pains and jaundice, but not so marked as in the catarrhal form. The symptoms of this condition vary widely, depending on the character and amount of the infection, at times closely simulating abscess of the liver, and have been mistaken for malarial fever on account of the type of the temperature and sweats. The differential points between these two conditions are as follows: In abscess of the liver we find that the patient prefers to lay with head and shoulder high and slightly on the left side, there is progressive and rapid emaciation and anemia, jaundice very rare. Grasping the liver in any location will cause pain, pressure under the costal margin with deep inspiration will cause pain. Local edema is sometimes present and is a valuable symptom. The right lobe is most often affected, enlargement of the liver is first in the upward and later in the downward direction. Temperature is often high, at first 103° to 105° F., but may begin insidiously, and become intermittent and irregular, with periods of normal temperature. Pains of a dull aching character in region of the liver and right shoulder blade. There is generally a history of some primary infection; constipation is quite marked, with occasional spells of diarrhea.

In suppurative cholangitis there is a history of biliary colic and transient jaundice; no enlargement of the liver, except in the severe grades of infection. Pain located at tip of the ninth rib, which is extremely marked, and occasionally a pyriform tumor, caused by a distended gall-bladder when the cystic duct is obstructed.

Cholecystitis may be acute, subacute or chronic, with or without associated gall-stones. The acute cholecystitis is due to infection by a variety of micro-organisms, most commonly *Baccillus coli communis*, and typhosus, pneumococcus, staphylococcus, and streptococcus. That cholecystitis can occur without the presence of gall-stones is an indisputable fact, but that this is a rare occurrence we must admit, and therefore, when symptoms are present which point to a cholecystitis we generally expect to find associated with it the presence of gall-stones, and are usually not disappointed. That a differential diagnosis between the calculous and the non-calculous form of cholecystitis is at times possible, I believe, by a careful study of the symptoms, but as the treatment is usually operative in either instance, this is of no great importance.

The symptoms are as follows: Acute paroxysmal pain, usually in the right hypochondrium, less commonly in the epigastrium or ileæ (appendiceal) region, is the earliest evidence of the disease, quickly followed by nausea, vomiting, abdominal distention, rigidity and tenderness. Tenderness is at first diffuse, later localized, but unfortunately not always in the region of the gall-bladder. Usually there is obstinate constipation and at times even complete intestinal obstruction, neither flatus nor feces passing. It is only recently that cholecystitis without gall-stones has been recognized as a pathological entity. Maurice Richardson declares that it is more frequent in his experience than many other supposedly frequent intra-abdominal lesions. The diseases most frequently mistaken for acute cholecystitis are intestinal obstruction, appendicitis, acute pancreatitis, and perforating gastric ulcer. *Acute intestinal obstruction* has many symptoms in common with gall-bladder disease; viz., pain, vomiting, constipation, tympany and collapse, but the temperature is the important differential symptom. An increase in the temperature of more than 1° to 2° F. excludes intestinal obstruction, as a rule, prior to the developing of peritonitis, and if a tumor develops in the gall-bladder region, the diagnosis becomes less difficult, especially if the tumor has the characteristics of a gall-bladder enlargement, to be described later.

Appendicitis.—Most mistakes are made in differentiating from this affection and are at times unavoidable, as occasionally the clinical picture is precisely the same. A careful study of the history is perhaps the best guide, and again, a tumor in either the appendical or gall-bladder regions makes the diagnosis comparatively easy; but when we remember that in appendicitis the pain is sometimes referred to the region of the gall-bladder, and in cholecystitis to the region of the appendix, and all the other symptoms, mode of onset, etc., are at times identical, an exploratory incision becomes our only means of arriving at a diagnosis.

Acute Pancreatitis.—The histories of both diseases are very similar, the digestive disorders common to both. Jaundice may be present or

absent in either. Both may begin with sudden and violent pain, usually more marked in acute pancreatitis, which is located in the epigastrium, to the left side, while cholecystitis is a right-sided affection. Tenderness is very deep-seated in pancreatitis, and quite superficial in cholecystitis. If tumor is present in either instance it is deep-seated and diffuse in pancreatitis and more superficial in cholecystitis.

Perforating ulcer of the stomach and duodenum have been mistaken for cholecystitis, the location of the pain and rigidity being our only guides. Cholelithiasis occurs mainly in women, the percentage ranging from 65 to 75 of all cases; especially after having given birth to children. The patient is usually between forty and sixty years of age and rarely under twenty-five years. Gormandizing, sedentary occupation, constipation and tight lacing are all predisposing causes that should be studied carefully. C. D. Mosher (*Johns Hopkins Hospital Reports*, 1901) gives the following conclusions for 1,655 autopsies (6.49 per cent. American to 12 per cent. German women): in other words, 1 in every 10 American women, and 1 in every 5 German women have gall stones. As to color, whites average 7.85 per cent. to 5.57 per cent. colored. An idea as regards the frequency of this disease can be gathered from Schroeder, who finds that 12.5 per cent. of all autopsies show gall-stones, and Kehr, who records 360 operations on the gall-bladder and ducts, of which 307 were for gall-stones.

Premonitory symptoms frequently occur, and are valuable aids to diagnosis. They are as follows: Constipation, flatulency, loss of appetite, vertigo, tinnitus aurium, migraine, urticaria, icteroid tinge, and scanty, dark urine. A combination of some or all of these symptoms should put us on guard for a possible oncoming attack of the so-called gall-stone colic.

Pain is sudden in onset and much diagnostic significance is attached to the time of its occurrence, which is usually at night, during the relaxation of sleep, but it may occur at any time; and any violent exercise, vomiting, coughing, etc., may precipitate an attack. In the beginning, the pain is usually located in the epigastric region. Later the right hypochondrium is affected and is ofter referred to the back, under the angle of the scapula; then the right shoulder and arm (*never down the arm*); rarely to the sacrum or hip. Pressure over gall-bladder will sometimes relieve the patient temporarily. The pain is intermittent, and may last from a few hours to a few days with complete or partial intermission. The pain is described as agonizing and much more severe than the pains of labor. The fact of the great suffering is depicted on the face, with marked depression, rapid respiration, cold sweats, frequently with a temperature of 103° to 104° F. Pulse rapid and weak, and at times weak, but slow.

Vomiting is usually present and is probably reflex. It seems to give temporary relief and not infrequently the colic disappears during an emesis.

Shock, of a varying intensity, occurs from a feeling of weakness to a condition of collapse, and death has occurred during the height of a paroxysm.

Pulse and Temperature.—There is quite some disagreement in reference to the pulse rate and the statement has been frequently made that a slow pulse is always present, but there are too many exceptions to this to allow it to be considered as a safe rule. If there is an infection the pulse is accelerated, and a persistent, rapid pulse is, as in all other abdominal diseases, of grave significance.

Temperature during the shock is often subnormal, but with a cold and clammy skin. The rectal temperature is sometimes found to be from 102° to 104° F., and in some patients chills and sweats, closely resembling malaria is present. Jaundice is a most unreliable symptom. From 1890 to 1902 Kehr performed 720 operations for gall-stones and jaundice was absent in 80 per cent. of the cases in which stones were located in the gall-bladder and cystic duct; and absent in 30 per cent. of the cases with obstruction of the common duct. When jaundice does appear, it usually comes on at the end of the first day or during the second day, after the acute paroxysm, and appears, first, according to Douglas, on the right side of the abdomen. Bile can often be found in the urine. The size and location of the stone, and the completeness of the obstruction determines the degree of jaundice, obstruction of the common duct being, therefore, more productive of jaundice than obstruction of the cystic duct.

Stools.—In obstruction of the cystic duct no decolorization of stools occur and in fact the obstruction must be absolute. It is a common occurrence to have marked jaundice with normal stools.

The urine shows bile pigment as a rule, but only when there is jaundice. The amount of urine is usually increased at first and contains some albumin and if the attack persists the urine becomes more scanty, and casts and albumin are usually found, and may be a forerunner of convulsion and death.

The local physical signs are of great importance and must be carefully studied. The tumor of the gall-bladder when present is a great help in making a diagnosis but, unfortunately, this does not always exist. In acute obstruction of the cystic duct a tumor is usually found and is typical, being round, smooth, and elastic, and when palpated and pushed away from the abdominal wall will return to the examining finger as if swung on a pendulum. In chronic cholecystitis with adhesion an irregular mass can sometimes be made out. The gall-bladder tumor responds to respiration. Crepitus can sometimes be felt. If Riedel's lobe can be felt with its sharp edge lying across the tumor it is pathognomonic of gall-bladder enlargement.

Roentgen rays have proven of but little value in the diagnosis of gall-stones.

In attempting to make a differential diagnosis in gall-stones we are at times compelled to eliminate almost every other intra-abdominal disease and in a short paper of this kind only the conditions which frequently and closely simulate it will be considered, and in order to avoid reiteration no mention will be made of acute intestinal obstruction, appendicitis, pancreatitis and perforating ulcers as they have already been described under the differential diagnosis from acute cholecystitis and will conclude with a few words descriptive of some other diseases that have been mistaken for cholelithiasis.

Gastralgia has been mistaken for gall-stones and diagnosis can be built upon the following points, found mainly in neurotic and hysterical patients: Pain comes when stomach is empty and is generally relieved by warm drinks or food. Pain is usually in the left side of hypochondrium and referred to left thorax. Pulse usually feeble and irregular, only slight tenderness and no tumor.

Non-perforating Gastric Ulcer.—Pain after taking food, often marked anemia, hematemesis frequent, and stools show some decomposed blood. Tenderness over seat of ulcer, also two inches to left of twelfth dorsal vertebræ, with rigidity of left rectus muscle.

Intestinal Colic.—Patients with this affection generally have diarrhea and some general muscular cramps; pain is referred to umbilical region with history of errors in diet or exposure to cold or exhaustion. Free bowel evacuation will usually cure and thus clear up the diagnosis. Malarial fever sometimes closely resembles calculus in the common duct. Quinine and blood examination will usually straighten out this tangle.

Carcinoma of Gall-Bladder.—Generally the patient is over forty years of age. Early cachexia, pain more constant and not so severe, jaundice comes on slowly and persists, enlargement of the liver, edema and ascites gradually develop and blood shows the usual changes found in carcinoma.

Movable Kidney.—Most frequent in thin and nervous women, pain in the lumbar region and referred downward, tumor is easily felt and grasped between the hands, not usually influenced by respiration. Shape is characteristic, and when mass is pushed back to its proper place in the loin, will stay there quite a time.

THE DIAGNOSTIC VALUE OF THE ROENTGEN RAYS.*

BY CHARLES LESTER LEONARD, A.M., M.D.,
OF PHILADELPHIA.

In dealing with the difficult problems of medical and surgical diagnosis, the practitioner is often confronted by a symptom complex that defies solution. As a result new methods of physical diagnosis have been developed and the resources of chemistry and physical science have been utilized. Physical diagnosis is thus largely based upon the discoveries of pure science adapted to its problems.

The rapidity with which the Roentgen rays have been developed into an accurate method of diagnosis shows a quick appreciation of their value to medical science. The expert diagnostician readily realizes the chances of error, and gladly welcomes new methods that will confirm his results. Thus, it has been, that the greatest encouragement in the development of methods of precision in applying these rays in diagnosis, has come from those most scientific and expert in medical and surgical diagnosis. They too, are the most eager to employ it, since it insures greater accuracy and confirms the diagnosis formed by other methods.

The late Dr. William Pepper appreciated the value of the Roentgen method in the diagnosis of thoracic aneurisms. In discussing the first series of these skiagraphs made for him in 1896, he said "that their value to him could not be expressed, since they formed a visible confirmation of the mental pictures he had been making for more than thirty years."

The particular element in this method that gives it precision and makes the data obtained more valuable is the mechanical element. The value of any physical method of diagnosis is increased whenever this mechanical element predominates over the personal element and eliminates to a greater degree the error always liable to be introduced by the personal equation.

Wherever the Roentgen rays have secured, mechanically, data upon which a diagnosis can be based, they have increased the accuracy. Their use does not wholly eliminate the personal equation or the skill of the observer. Sufficient of these elements enter into the final results to frequently render them far from accurate. The skill and experience of the diagnostician must always be taken into consideration. Equally good results should not be expected from the expert and the novice. The utmost care and attention to detail, and a full knowledge of the instruments he is using, are demanded of the expert to obtain accurate results. The necessary knowledge and technic are not readily acquired and earnest study is demanded of the student if he would learn to avoid errors. The apparatus and the method have often been blamed for the inexperience and errors of the observer. Clinical experience is of equal value in this as in other

* Read by invitation before the Medical Society of the State of New York, October 13, 1903.

methods of diagnosis. The expert diagnostician with other methods can acquire skill with this method and in its interpretation with greater ease than the inexperienced. His clinical knowledge of conditions and possibilities leads him to employ it more efficiently.

The mechanical element does not enter so largely into the fluoroscopic method of diagnosis. The data obtained are not registered mechanically on a photographic plate, but are only caught upon the retina. The result is that these data are often what the observer thinks he sees and not what exists. Valuable data can undoubtedly be obtained by the study of the fluoroscopic picture, as well as expertness in its use and interpretation, but it can never approximate the accuracy of the skiagraphic method, since it lacks the mechanical element of registering the observation.

A review of the entire field in which the Roentgen method has demonstrated its diagnostic value, or even a brief discussion of its advantages in its varied applications, is impossible in the limits of this paper. I shall, therefore, confine myself to a discussion of its value and advantages in calculous nephritis and ureteritis. The conclusions deduced are based upon the study of three hundred cases that have been referred for examination and diagnosis. The advantages demonstrated are a greater accuracy than other methods of diagnosis. An equal accuracy in the positive and negative diagnoses. A freedom from all the dangers and inconveniences common to exploratory operations, vesical examinations and ureteral catheterizations. The possibility of an early accurate diagnosis as soon as the suspicion suggests the possible presence of a calculus. A greater comprehensiveness definitely excluding or locating all calculi; giving their size, location and number, whether one or both kidneys and ureters are involved. This greater detail in diagnosis localizes and limits the operative intervention. It renders incision into the kidney unnecessary, except for macroscopic lesions; and has given rise to a conservative expectant line of treatment, that is rational, because it guards the integrity of the kidney.

An analysis of the three hundred cases that have been examined shows that calculi have been found in 86 cases, or over 28 per cent. That in 46 of these cases, or over 50 per cent., the calculi were in the ureter. That in nineteen of these cases of ureteral calculus the patients passed the calculi after expectant treatment had been suggested as the result of the Roentgen examination. The positive diagnosis has been confirmed by operation in all cases operated upon except five. In two of these cases the operation was delayed more than a month after the diagnosis had been made. As these were both small calculi it is very possible they had passed. The author has frequently advised immediate operation, or the repetition of the examination before operation if it has been delayed, and the search of the bladder just prior to operation with a Bigelow's evacuator, in all cases of small calculi. In two of my cases the stone has passed into the bladder between Roentgen examinations, and has been subsequently detected after its passage through the urethra. In a third case the interval was not so long, but the vesical examination was omitted, though the patient had had an attack of colic between the examination and the operation. In the two cases where the operators failed to find renal calculi the patients weighed over two hundred pounds and were corpulent. The diagnosis rendered in each case was probable stone or incrustations of crystals with a mass of débris in the pelvis of the kidney. This diagnosis was necessary because the plates did not have sufficient definition to warrant an absolute diagnosis of stone. In one case it was impossible to repeat the examination and in the other the danger of burn made it seem unwise. In one nothing abnormal was found to account for the symptoms, but the patient recovered and is still in the best of health. In the other a mass of pus and crystalline débris was found. In both cases operation was absolutely necessary.

The ease with which calculi can be overlooked during an operation is illustrated by the following case: Mrs. M., about forty-five years of age, quite stout, had suffered for the previous five years with a constant dull ache in the right hypochondriac region with frequent exacerbations of pain. Urine was cloudy, showed pus, uric acid crystals and red blood cells. A Roentgen examination showed a fairly large calculus, the shadow was not very opaque. She entered a hospital two weeks later where they failed to find the calculus by the Roentgen examination, and also in the subsequent operation. She came under the care of Dr. G. G. Davis eight months later with a persistent urinary fistula. He operated and removed a phosphatic calculus thus confirming the diagnosis.

The negative diagnosis has been found as accurate as the positive and even more so. This diagnosis has been found correct in 45 cases that have come to operation after the negative diagnosis had been made. In one case, previously reported, a large calculus was found, the error being due to faulty technic in placing the plate and in the subsequent reading. In two other cases small calculi have been passed after the negative diagnosis had been rendered. The negative diagnosis has been confirmed in many other cases by their subsequent developments. In two case phleboliths have been found that suggested ureteral calculi. One was known to be present in the wall of the vagina, and the multiple phleboliths eight in number in the other case were found on operation in a varicocele of the veins of the broad ligaments. This patient had had for a long time obscure symptoms. The ligation of the varicose veins resulted in her cure.

The total combined error in both positive and negative diagnoses is less than three per cent. This method has never been considered infallible, but the amount of accuracy obtained is greater

than that of any other method. Equal accuracy is claimed for the negative and positive diagnosis. This claim was made by the author for this method in 1898 and his results since that time justify the claim. In every case all the knowledge that can be obtained by all methods of diagnosis is none too much, and every case should be carefully studied by all means at command including the Roentgen method.

The further value of this method, in directing and facilitating operation, and in rendering operation unnecessary and expectant treatment safe, will be illustrated by the study of certain cases and groups of cases, in which its effects upon operative procedure have been shown.

The group of 19 cases in which the expectant line of treatment was advised and resulted in the passage of the calculi without operation, shows the advantages of this method as a basis for treatment. It is more accurate, as shown by the increased ratio of ureteral to renal calculi. Fifty per cent. of the calculi detected entered the ureter before producing sufficient symptoms to call for the attendance of a physician. It is highly probable that many more pass through the entire urinary tract; while post-mortem findings show that many calculi remain undetected in the kidney without producing symptoms.

Undetected quiescent calculi, especially if small, are a constant menace to the integrity of the kidney. They may have already occluded the ureter, or they may at any time do so and produce a unilateral anuria and the destruction of the kidney, or even complete anuria that will threaten the life of the patient. The subsidence of symptoms after an attack of ureteral colic is no guarantee that the calculus has passed or that the urine is able to flow past it. Complete obstruction menaces the functional life of the kidney, and yet all symptoms may subside and the condition absolutely simulate recovery. They can only be differentiated by the observation of a bilateral urinary flow with the cystoscope. The condition is entirely altered by the recognition of a calculus and the determination of its absence after the subsidence of symptoms, or after all those that have been detected have been passed.

The recognition of the presence, position and exact size and number of these small calculi has rendered rational a course of treatment that would otherwise be extremely hazardous. It has also justified the establishment of an expectant conservative line of treatment in cases where calculi are found small enough to pass through the ureter. Such an expectant conservative treatment was suggested by the author more than two years ago, as the result of his experience with these calculi (*American Medicine*, November 30, 1901). That such treatment is justified is proved by the series of 19 cases in which such small calculi have been passed. The period between their detection by the Roentgen rays and their passage has varied from five days to eight months. Such a course of treatment cannot be advised until a careful study by other methods has been made, and then the patient must remain under careful medical supervision. Immediate operation is sometimes necessary or may be called for by threatening symptoms. It has been necessary in three of my cases. In the first the diagnosis was made during an acute attack. There were no symptoms of progression on the part of the calculus, the pain was constant and severe, and the temperature pointed to infection. The calculus had been located an inch below the lower pole of the left kidney and was removed by direct ureterolithotomy. The wound healed rapidly and the patient made a complete recovery. The calculus was of the mulberry variety and very rough. This accounted for the intense pain, the difficulty in passing and the final impaction. In a second case impaction was complete at the point where the ureter crosses the common iliac artery. In this case all pathological elements were absent from the urine. The calculus was removed by a transperitoneal ureterolithotomy.

The third case was of special interest and illustrated as well, the precision of this method and the minuteness of the calculi that can be detected: A young married woman, of twenty-six years, had had a series of severe attacks of ureteral colic. She was examined at her home between attacks. Three very small calculi were found in the juxta-vesical portion of the ureter. The series of colic attacks made it seem probable that they would be expelled. The symptoms became grave and operation was necessary. It showed the three calculi in the exact position indicated, completely obstructing the ureter. They were removed and the pyonephrosis drained. The patient has completely recovered. In none of these cases was it necessary to explore the kidney.

Another group of cases illustrates the inaccuracy and incompleteness of operations without the aid of this method. They also show how this method increases the precision and completeness of operations and decreases the amount of operative trauma. The increased detail afforded by this method of diagnosis guards against the errors which were formerly made where there were multiple calculi in kidney and ureter, or in both urinary tracts at the same time. The position of all calculi is now determined before the operation is commenced. In three cases calculi have been found by the skiagraph in one kidney after operation upon the other, and in two of these cases calculi had been overlooked in the kidney operated upon. In another case an operation disclosed a fascetted calculus, the patient was too weak for the search to be continued; further operation was postponed and a Roentgen diagnosis made. This showed ten calculi remaining, located in both kidneys and ureters. They were all removed at later operations and the patient made a complete recovery.

In three other cases previously reported calculi were found at the operation, only because they had been previously located by this method. In three cases persistent urinary fistulæ, following unsuccessful nephrolithotomy, were found to be

due to calculi that had not been found, blocking the ureter. Operative procedures have been facilitated in many other ways. Calculi have been removed through incisions that just admitted a finger that were made directly on the calculus, thus decreasing the trauma and operative risk. Others besides those mentioned previously have been removed by ureterolithotomy, either transperitoneal, rectoperitoneal, through the vaginal vault or through the bladder. In all these cases it was unnecessary to touch the kidney.

The accuracy of the negative diagnosis is attested by the 45 cases that have come to operation after this diagnosis had been rendered. In some of these cases the surgeon expected to find a calculus, but in only one case has a calculus been found.

This accuracy has led to the belief that where an accurate Roentgen diagnosis shows no calculus is present in the kidney, incision into the kidney is not justified, during an operation otherwise indicated, unless some other macroscopic pathological lesion is present.

In a case recently examined a negative diagnosis was rendered. The definition was so clear that a displaced left kidney could be seen, its lower pole on a level with the crest of the ileum. Such a displacement was sufficient to account for the symptoms and so much definition clearly excluded all calculi. The kidney was, however, opened during the nephrorrhaphy and a search for calculi was made, thus increasing the operative risk. The patient unfortunately died.

In favorable cases, that is, in patients weighing under 140 pounds, detail can often be obtained of the soft tissue structures that will suggest some condition other than calculus that is present. Thus displaced kidneys, pyo- and hydronephroses and even small collections of pus in the pelvis of the kidney have been observed and afterward confirmed by operation. As small an amount as an ounce of pus has been recognized by a shadow and subsequently removed by catheterization. The mottled appearance presented by the tuberculous or cystic kidney has sometimes been noted. These detailed diagnoses are exceptional and can as yet be made with no certainty and only in favorable cases.

The accuracy that has been obtained in calculus diagnosis is the result of an improved technic, further improvements may result in greater accuracy in other fields.

The author's technic in calculus diagnosis is based on the axiom that where shadows less dense than the least dense calculus are obtained no calculus should escape detection. Accurate results in both the positive and negative diagnosis can be guaranteed by a technic capable of making such negatives and clinical experience that can recognize when they have been obtained, and read them correctly.

The essentials of the technic developed and used by the author in this series of cases are: a self-regulating tube that will maintain itself at a low vacuum steadily during the entire exposure, thus guaranteeing the non-penetration of the calculus. It must be possible to repeat the exposure at any later period under identical conditions. The coil or source of electrical energy must produce a large volume of Roentgen rays of low penetrating quality.

One of the greatest difficulties in Roentgen work is in recognizing when the tube is producing the requisite volume of Roentgen rays. The vacuum of the tube bears a nearly constant ratio to the penetrating quality of the rays, but varies with the kind of tube and the form of apparatus used to energize it. The vacuum employed by the author is equivalent, on his apparatus, to a parallel spark in air measuring 1½ to two inches. Unfortunately this measurement is only relative and accurate only for similar apparatus. The Roentgen ray producing efficiency of various types of apparatus can only be measured by experience. A technic developed with any combination of apparatus, which can consistently produce negatives containing the necessary amount of definition, if a low vacuum tube is used, should be capable of making accurate negative and positive diagnoses. The low penetrating quality of light is essential to prevent the penetration of small uric acid and phosphatic calculi. The ability of the tube to maintain steadily the desired degree of vacuum is of the greatest importance as any variation results in the penetration of these less opaque calculi.

The value of the Roentgen method of diagnosis in this field has been demonstrated to be greater than any other known method. It has already rendered operation unnecessary in a number of cases, and has increased the value and efficiency of operation, while lessening its dangers and minimizing the amount of operative trauma.

THE VALUE OF CLIMATE IN GENITO-URINARY TUBERCULOSIS.*

BY W. H. PRIOLEAU, M.D.,
OF ASHEVILLE, N. C.

IN the accepted hygienic and dietetic treatment of tuberculosis of the lungs, one of the most important laws laid down, is that the patient should, if possible, seek a change of climate so soon as the disease is recognized. This should apply not alone to the victim of pulmonary tuberculosis, but equally so to the tuberculous disease when located elsewhere, whether in the larynx, kidneys, bladder or joints.

When the lungs only are infected, a cure is much more favorable than when any other organ is the seat of the disease. There are several apparent reasons for this—the diagnosis is made much earlier in pulmonary tuberculosis and the disease is generally confined to the lungs; whereas when any other organ is tuberculous, the process, as a rule, is secondary. At the same time, if the infection happen to be a primary one, it is

* Read by title at the Second Annual Meeting of the American Urological Association, May 8 and 9, 1903, New Orleans, La.

rarely recognized as such in time for successful treatment to be commenced. For example, a patient comes to the office, complaining of weakness, extreme lassitude and drowsiness in the afternoons, some slight morning cough and perhaps a little expectoration; at once, even without waiting for the tubercle bacilli to be found in the sputum, a diagnosis of incipient infection of the lungs is made and systematic treatment is begun.

Again a patient consults you about a frequency of urination, possibly he has the morning drop or may be a slight watery excess from the urethra. Almost the last disease one would think of would be a tuberculous eruption of some part of the genito-urinary apparatus. More than likely it would be considered the result of a venereal infection; especially so, if the patient had ever had specific urethritis. If, when the disease is primary, it were recognized in its incipiency, I believe the results would be almost, if not quite, as good as are now obtained in pulmonary tuberculosis.

It is an acknowledged fact that the hygienic-dietetic treatment of tuberculosis of the lungs yields the greatest number of cures when begun in the pretubercular stage of that infection; the same may be expected in genito-urinary tuberculosis, provided we begin our treatment sufficiently early.

The constitutional treatment of tuberculosis, wherever the process may be located, is the same. Such being the case, we know that climate is a powerful adjuvant to our treatment. It has been my limited experience that that climate which gives the best results in pulmonary tuberculosis also does most good in tuberculous infections of the genito-urinary apparatus. The mountain climate of a moderate elevation, where the air is dry and there is a maximum of sunshine throughout the year, offers, as a general rule, most to the tuberculous invalid, no matter where his infection is located. As there are exceptions to all rules, so not infrequently do we find cases which respond to treatment more readily at the seashore, or in the pine-land region, only a few feet higher than the sea-level. This is apt to be the case with those infections contracted in the mountains, and also with renal tuberculosis. At no time should a patient with tuberculosis of the kidney be sent to an extreme altitude; the increased heart's action caused by the elevation adds more work to the already inflamed kidney and thus does away with the benefit which might otherwise be expected from the climate.

As a general rule, it might be said that a moderate altitude, when it suits a case, is the most desirable; for when a patient regains his health at such an elevation he can return home with less likelihood of the disease reappearing; whereas, if he had regained his health at a very high altitude, it is questionable whether it is ever advisable for him to leave there.

While climate is a most valuable adjunct to the treatment of genito-urinary tuberculosis, at the same time it cannot effect a cure by itself. More important even than climate is diet; and then come the adjuvants, according to the organ or part of organ diseased. It is true of the tuberculous invalid, as it is of the healthy man, that it is only the assimilated food which nourishes the body. Superalimentation most undoubtedly does harm in urinary tuberculosis.

Excessive ingestion of food means extra work for the kidneys, besides the overproduction of uric acid xanthin, etc. The extra work imposed on a diseased organ would produce sufficient injury by itself; but along with the increased work, we have the passage of irritants through the kidneys, bladder and urethra. If any of these be diseased, the inflammation would be increased by the acid urine. Just as we avoid overfeeding because of the extra work and production of irritants, so we eliminate from the patient's diet all foods and drinks which are known to be genito-urinary irritants; namely, tomatoes, strawberries, condiments, alcohol and carbonated waters.

If the sexual apparatus is the seat of disease we should endeavor to have the patient control his feelings as much as possible and avoid all mechanical irritation.

Instrumentation of the tuberculous genito-urinary apparatus is seldom advisable; the friction caused by the passing of an instrument over a localized tuberculous spot only increases the process.

In all cases of genito-urinary tuberculosis, we must rely on hygiene and diet; and as adjuvants, use urinary antiseptics and sedatives; always remembering to select a suitable climate for the patient, as you would do were his lungs diseased.

SEASICKNESS.

BY WILLIAM F. WAUGH, A.M., M.D.,
OF GREEN BAY, WIS.

If anyone possesses a theory as to the treatment of seasickness, he should be very careful of it, as it is fragile property, easily damaged. Especially should he avoid the vicinity of water, for dampness is fatal to it. The theory should not be allowed to come within 100 miles of a steamer.

Leaving Chicago Saturday evening, on Sunday we encountered a brisk head wind; the waves tumbling in confusion, and here and there a white cap. Nothing special to a man who has seen Old Ocean in his boisterous moods, while Boreas played horse with him—and yet of our 100 fellow-passengers nearly all succumbed. The writer, old sea-dog too, surrendered at once; but he is an expert in this malady, feeling its effects always by car, even on the city cable cars or in a carriage. And yet the good ship "Georgia" did not roll and only pitched gently with a long easy swing that had no savor of the disagreeable in it. If this note, perchance, catch the eye of anyone who voyaged in that ancient tub the U. S. S. Swatara, second rate, and recollects the roll of 42 degrees—sideways—and the combined pitch—

fore-and-aft—ending with a jerk like the crack of a whiplash, they—well, they haven't forgotten.

The theories as to the nature and causes of seasickness are good—all of them. Possibly some of our fellows in misery were bilious, probably some had overloaded stomachs and bowels; but obviously this does not account for the unanimity with which all paid tribute to Neptune's representative on these waters. Ocular deficiencies may have a part, for the unaccustomed strain on the accommodation proves trying, and induces headache, relieved by closing the eyes.

But there appears to be a state induced in most persons by the unaccustomed motion that is analogous to that caused by snake venom—a paralysis of the abdominal vasomotors with accumulation of the blood in the viscera and consequent anemia elsewhere, especially in the brain. *Hinc illæ lachrymæ*—hence the gastric hyperesthesia. And is not the stomach hyperesthetic! Mark Twain remarked: "On the second day out I hove up my immortal soul." And really, our hopes too, for after completely emptying ourselves we took a minute granule, but the stomach found it and brought it up—and we really hope the soul is not still more infinitesimal.

Now, if this vasomotor splanchnic paresis theory is good, the same remedy that has proved effective in snake bites should answer here—strychnine, in doses enough to restore a normal pulse. It has already been shown that atropine, just enough to obviate the cerebral anemia, will relieve in many instances; and yet the strychnine seems more directly applicable. There is no reason why they should not be given simultaneously, as in this instance they are synergistic. Or, better, give in alternation, since each has its own indication of full effect. Give to an adult atropine gr. $^1/_{1000}$ every ten minutes until slight dryness of the mouth is felt. This is invariably the first evidence of its action, and neither dilatation of the pupils nor flushing of the face are requisite for the full therapeutic effect, except in cases of hemorrhage, where it is an object to get the blood into the cutaneous capillaries and out of harm's way as quickly as possible. The therapeutist, whose work is regulated with precision, will suspend atropine as soon as the mouth begins to be dry, and administer another dose of similar dimensions only when the dryness begins to subside. In this way all unpleasantness is avoided and yet the full benefit secured.

Strychnine should be given in doses of gr. $^1/_{134}$ —half a milligram—every ten minutes until the pulse has acquired normal tonicity, and thereafter just often enough to sustain this effect. This allows for all possible variations as to susceptibility, idiosyncrasy, degree of severity of the attack and obstinacy of its effects, etc. To those unaccustomed to dosage regulated by effect, the quantity required in some instances will seem enormous, even perilous; yet nothing is safer, surer. If gr. $^1/_{40}$ of strychnine is sufficient to relieve the vasomotor paresis present, give that much and then stop it; if the depression is so profound that half a grain is required to restore tonicity, give that and quit—or rather follow with enough to maintain the effect, since the cause is continuously acting.

And do not let the patient mope. The best way to be seasick is to sit gazing at the waves and think how sick you are. To deepen and prolong an attack, go to bed and give up. "Resist the devil and he will flee from you," and no one who has suffered with this fiendish malady will for a moment doubt its satanic personality. Resolutely walk it off; keep busy; get the thoughts off yourself and on anything capable of distracting the mind from introspection; and the attack will be soon over. Was there ever a case of such severity as to justify the recommendation of a Frenchman, to stupefy with chloral and remain in that condition during the entire voyage?

Anticipate the voyage by clearing out the alimentary canal and practise a salutary abstinence before and during the trip. Determine not to give up if taken, but fight it out. Take the remedies advised, in a spoonful of hot water—the naked alkaloids are thus very quickly absorbed and the hypodermic syringe is superfluous. Don't take all the numerous remedies suggested but cling to a really scientific treatment, based on a clear idea as to the pathology.

Have I tried this theory in practice? Well, no; not yet. You see it is still young, just new-born in fact, and one should not recklessly expose it to the whims and arrows of outrageous fortune, until it has gained some strength.

MEDICAL PROGRESS.

MEDICINE.

Acute Dilatation of the Heart.—A most interesting and exhaustive article by D. DE LA CAMP is contained in the Zeitsch. f. klin. Med., Vol. 51, Nos. 1 and 2, and materially increases one's knowledge of the etiology of acute dilatation of the heart. In all the experiments the size of the heart was measured by the Roentgen rays, so that the results must be looked upon as absolutely accurate. In the first series, a large number of patients were requested to work a specially constructed apparatus to the limits of endurance, and the skiagraph was then compared with the one taken several hours before. The endurance was greatest in convalescents from mild disease, least in those afflicted with neurasthenia and hysteria, but an increase in cardiac volume, sufficient to warrant a diagnosis of acute dilatation, was absent, even in myocarditis and endocarditis. Only one girl, suffering from severe loss of compensation, secondary to a mitral lesion, presented a marked increase in size after a walk of one hour, which considerably taxed her strength. Healthy porters were then instructed to wrestle up to exhaustion, with absolutely negative results, even when circulation was embarrassed by a tight band around the abdomen and dyspnea and cyanosis were marked. Large doses of alcohol and forced respiratory movements were also without result. The following experiments were then made with animals: (1) A dog is forced to rotate a wheel until exhausted for several days in succession, so that the animal finally dropped as if dead. No increase in vol-

ume could be detected. (2) The vagus was irritated with the faradic current till heart action ceased. An acute dilatation of the ventricles set in. (3) Traumatic aortic insufficiency had no effect. (4) Introduction of air into the veins caused death by acute dilatation. (5) Saline infusion till the heart stopped beating was without influence. (6) A fatal dose of digitalin caused contraction of the ventricles and dilatation of the right auricle, with general change in shape. (7) Muscular exertion after daily venesections and starvation had no effect, but acute dilatation was very marked, if the animal was fatigued after the contents of a tuberculous cavity or some other toxic material was injected. (8) Phosphorus and oil of pennyroyal caused a fatty degeneration of the heart, and some relaxation, not amounting, however, to dilatation. (9) A strange behavior was noticed when all extracardial nerves were severed, the animals became fatigued after the slightest exertion, yet the heart-shadow remained nearly normal. All the experiments proved that a normal heart, or one the seat of only slight lesions, is incapable of overdistention, no matter how its working-capacity is taxed. The records of a number of cases of dilatation observed by the author are in accord with this, for in all there was some serious lesion. In the non-fatal cases this may not be evident; the heart may possess its normal size and beat normally after the attack is over. But a careful history and examination will always disclose some previous, not necessarily severe, infection or some chronic systemic derangement, which is sure to alter the heart muscle. It cannot, however, be denied that the healthy heart may occasionally dilate when several injurious factors act upon it at the same time. Thus, besides overexertion, there may also be the coincident ingestion of too much fluid. Soldiers marching long distances, when heavily laden, sometimes suffer from attacks and the effects of rarified air in mountains are undeniable, though not readily explained.

Palpation of the Pylorus.—Many patients have been sent to P. Cohnheim (Deutsch. Arch. f. klin. Med., Vol. 78, Nos. 3 and 4), with a diagnosis of carcinoma of the stomach, and yet presented only a normal, large pylorus in an abnormal location. Pseudotumors of the abdomen generally include abnormal contraction of the recti muscles, hypertrophic left lobe of the liver, thickening of the aorta and adhesions about the smaller curvature, but a normal pylorus may also impose as a neoplasm. It is generally found in thin people with relaxed abdominal walls and often diastasis of the recti exists. A large number of the patients are consumptive. The condition may sometimes be diagnosed by seeing the pyloric contractions, but far more often they can be felt moving from left to right if the hand is placed lightly upon the tumor after the patient has swallowed some water. A hard tumor will alternately develop and disappear. The contractions are usually not painful, unless an ulcer or pyloric fissure is present. If the tumor does not soften and disappear, but remains permanently hard, a carcinoma is probably present.

Rare Complications of Carcinoma of Stomach.—A patient suffering from an inoperable carcinoma of the pylorus was subjected to gastro-enterostomy by F. Kaufmann (Münch. med. Woch., Nov. 10, 1903), when severe motor insufficiency and intestinal stenosis developed several weeks after the operation, and the patient finally died of perforative peritonitis. Involvement of the intestines in gastric cancer is not rare; the stools are said to be normal throughout the course of the disease in only 4 to 5 per cent., and in fully two-fifths constipation persists at first and diarrhea later on. Stenosis, however, is very infrequent and may be due to the primary tumor, where the ligaments are so short that the colon cannot be displaced, or to growth in the intestinal wall itself, either by extension or metastasis. A gastro-colon fistula with feculent vomitus would speak for extension, but generally the exact diagnosis is impossible. In a second case, a stenosing carcinoma of the cardia, complicated by pyloric stenosis, due to metastatic glands, was found to explain the high degree of dilatation and motor insufficiency in a stomach whose cardiac orifice could hardly be passed by a sound. A similar condition is sometimes brought about by direct extension of the carcinoma or by involvement of the vagus branches, or by two independent tumors.

Method of Using Antitoxin.—Few physicians now hesitate about the use of antitoxin in diphtheria, but there is considerable difference of opinion in regard to the dosage and the frequency with which it may be given. The rule seems to be to give a full dose, which varies greatly with the age of the patient, the severity of the disease and the physician's personal opinions, and then repeat the dose in twelve to twenty-four hours. This frequently requires very large doses, and in very severe cases is sometimes inefficient. C. F. Welden (N. Y. Med. Jour., Nov. 14, 1903) has changed this method somewhat by giving a moderate dose, about two thousand units, and repeating it every three hours till results have been obtained. In this way toxic symptoms may be avoided, and the system more quickly brought under the control of this agent.

Treatment of Pulmonary Tuberculosis with Raw Meat.—This is an investigation based both on private and hospital practice. B. S. Knotte (Roussky Vrach, Nov. 1, 1903) reports in detail the case of a neurasthenic thirty years of age, who had suffered ten years ago from syphilis for which he received specific treatment. For the last three years patient showed undoubted symptoms of pulmonary tuberculosis. He was put under treatment for three months, during which time he was fed with fresh meat-juice, expressed from raw meat; later on he was also given between 80 to 100 grm. of meat without the fat. During all this time he was attending to his business as usual. The author states, however, that instead of improving the patient grew gradually worse, so that the treatment had to be discontinued. It was only a second course of treatment extending over a period of five months, which seemed to be of very great benefit to the patient, so that the author could find permanent and stable improvement. In the other cases, some of which were in an advanced stage of the disease, the author was guided in administering the juice by the patient's ability to digest it, for to some it was so repugnant that they could not be persuaded to drink it. The quantity of meat ingested was between 300 to 650 grms. per day. At the same time the usual tuberculous treatment was not set aside. Although no cure was noted there was an undoubted improvement in many of the cases, and the author unhesitatingly advises the treatment in cases where climatotherapy is beyond patient's reach. Proper care should be taken of the functions of the liver and kidneys. The gist of this method of treatment lies in energetic feeding. But the author is also inclined to attribute to raw meat or juice a sort of specific effect on the tuberculous process.

Death from Acute Circumscribed Edema.—Cases of localized edema appearing rapidly in certain parts of the body without any known cause and in a few hours or days as quickly disappearing, were first reported by Quincke in 1882. Only two instances of death have been mentioned as resulting from this cause, and they were due to the fact that the edema involved the upper air passages and caused immediate suffocation. E.

STRÄUSSLER (Prog. Med. Woch., Nov. 12, 1903), reports the case of a soldier, twenty-three years old, who was suddenly awakened in the night with a feeling of suffocation, and although medical assistance was near at hand, he died before a tracheotomy could be done. He previously had been confined to a hospital for a few days on two occasions suffering from edema of the scrotum and penis. A history was obtained that his father and a brother had suddenly died from suffocation without known cause, and heredity seems here to have been an important factor. An autopsy failed to disclose any lesions of the heart, lungs, kidney or liver and the circumscribed swelling of the tissues of the neck and larynx were the only discoverable pathological lesions.

Diagnosis of Diabetes.—Although the diagnosis of this disease depends upon an examination particularly exact in its findings when properly done, yet there are several reasons why mistakes are frequently made. R. T. WILLIAMSON (Med. Chron., Sept., 1903) shows how often the disease is overlooked because the prominent symptoms are not complained of and no urine examination is made. Loss of flesh and increasing weakness may be the only symptoms for months. Pruritus of vulva and eczema of external genitals may be first indications of diabetes. Defects in vision, phthisis, carbuncles or attacks of pains in the legs of an irregular type accompanied by loss of knee-jerks, but no other tabetic symptoms, may lead to the suspicion that diabetes mellitus is the true cause. Coma may even supervene before a true diagnosis is made. On the other hand, small quantities of sugar in the urine may be held responsible for too many of the symptoms of which the patient complains, and it is necessary to be sure that we are not dealing with a simple, temporary glycosuria, or that the reaction is not due to some other reducing agent in the urine. In the examination of urine for sugar in most cases Fehling's solution is the only test required. If no oxide of copper be thrown down on boiling, and if no greenish precipitate appears when the mixture cools, then sugar is absent in a clinical sense. If a precipitate is present and the other symptoms are present, the diagnosis of diabetes is justifiable. If, however, the precipitate is very slight and there are no symptoms present the question arises whether the reaction is due to sugar or some other reducing agent such as lactose, pentose, uric acid in excess, glycuronic acid, alkapton, etc. The phenyl-hydrazin test is the best to apply in these cases, and a simple modification of it may be done as follows: A test-tube of ordinary size is filled for about half an inch with hydrochlorate of phenyl-hydrazin, then acetate of sodium, in powder, is added for another half inch. The test-tube is half filled with urine and boiled for about two minutes. After standing a half hour the sediment at the bottom is examined under a microscope. If glucose is present bright sulphur-yellow needle-shaped crystals will be found. It is so sensitive in its results that crystals will be present when only 0.015 per cent. of sugar is present. Glycuronic acid is practically the only other substance which will give these crystals. If it is desirable to be absolutely sure that these tests are caused by glucose, the fermentation test may be tried and glycuronic acid will give no reaction in this case.

Infectious Diseases among Negroes.—The experience of many years as physician among the tribes along the west coast of Africa are embodied in an article by A. PLEHN (Virchow's Archiv, Vol. 174, suppl.). It is an interesting fact that the uncivilized negro is almost immune toward many infectious diseases which are common and fatal among the whites, but that he has in malaria and dysentery formidable enemies which oftentimes decimate his rank. Tuberculosis, scrofulosis and rachitis are hardly ever seen, syphilis is rare and runs a mild course, tabes and progressive paralysis has never been observed, and only a few cases of malignant tumor and leprosy have been met with. Even contused wounds heal rapidly, and if an infection occurs, it is generally mild and circumscribed. Despite indiscriminate sexual intercourse, gonorrhea is not usually followed by its disagreeable sequelæ, and sterility among women is not encountered often. Diseases which do not occur at all are anthrax, glanders, hydrophobia, diphtheria, and scarlet fever, while measles is common, though mild. Smallpox plays an important rôle in the tropics, but it often appears more like a skin-disease than a constitutional infection. Vaccination does not seem to protect as well as in Europe. The negro race seems to be rather insusceptible toward yellow fever, and plague, exanthematic typhus, cholera, recurrent and Malta fever are only introduced occasionally. Typhoid, on the other hand, is more common and presents the usual course, except that diarrhea is often absent, and cerebral symptoms are especially marked. A large percentage of cases are not real typhoid, but colon infections. The most important disease undoubtedly is dysentery of amebic origin, though it also runs a mild course, and is readily controlled with calomel and bismuth. Pneumonia presents the following peculiarities: It frequently begins centrally, often affects one or both upper lobes, and the local signs may change place. The onset is not acute, but slow, with bronchitis. Serous exudation into the pleura does not complicate the disease, which seems to speak for the tuberculous nature of the former. Mumps is frequent, and mild and acute articular rheumatism frequently attacks the natives, causing considerable suffering, but never involving the serous cavities or the endocardium. Most cases of beriberi run very acutely and are often fatal in twelve to forty-eight hours. The entire symptom-complex points toward a severe infection, involving especially the sympathetic and vagus nerves; despite abundant material it was, however, impossible to determine the nature of the poison and its probable portal of entry. No drug has a favorable influence upon the disease and morphine, which must be given freely on account of the intense pain, seems to hasten the end. The condition of the liver at autopsy is interesting, since it often shows interstitial changes, besides marked degeneration. The opportunities for studying malaria are especially favorable in western Africa, since it forms a veritable scourge for the black race. It is a mistake to believe that one attack protects from others, though it is common to find plasmodia in the blood as harmless parasites, without causing fever. Even young infants are as a rule infected, though not ill. The parasites are not entirely latent in these cases, since an anemia with splenic tumor will gradually develop. The blood examination is of less value for the diagnosis of an obscure disease, since one cannot always tell if the plasmodia are active and latent. A relative immunity is frequently seen, so that subsequent attacks are much milder, and this may account for the low mortality. All three forms of parasites, together with transitional types in all possible combinations, may be detected in the blood in actively infected negroes. Quinine generally acts very promptly. In conclusion, the author states that the remarkable resistance of the negro cannot alone be explained by the absence of alcoholism, tuberculosis and syphilis; it is a racial peculiarity which is gradually lost with civilization.

Infection with the Bacillus Typhi Murium.—Cultures of the *Bacillus typhi murium* are frequently employed to kill mice, and hitherto no infection in man

has been observed, so that the germ was considered harmless until R. TROMMSDORFF (Münch. med. Woch., Dec. 1, 1903) had occasion to observe a small epidemic in a village. The symptom developed two days after infection and merely amounted to a moderate diarrhea of two to seven days' duration, vomiting in a few cases and a mild prostration. In only one instance did the disease prove fatal, owing to a general poor condition of the patient. The bacilli were found in large numbers in the cholera-like stools, and were readily agglutinated by the blood-serum of the convalescents.

Determining Pressure in Right Auricle.—G. GARTNER (Münch. med. Woch., Nov. 24, 1903) has discovered a very simple method of measuring the pressure in the right auricle. If the veins of the arm are observed while the arm is hanging by the side of the body, they will be found filled, but as soon as the arm is raised beyond a certain level, they collapse and become invisible. The distance between this level and the right auricle accurately corresponds to the auricular pressure. In normal individuals the phenomenon is noticed when the arm is raised to the level of the fifth, fourth or third rib; in pathological cases it must be elevated to the jugulum sterni, sometimes even to the level of the eyes or the top of the head. The measurements should always be taken from the upper border of the fifth rib at its sternal insertion; though this does not correspond exactly to the position of the auricle, it is a fixed point concerning which there can be no doubt. The highest figures obtained were 37 centimeters in a case of beginning infiltration of both apices. In pulmonary infarction a marked fall was observed after an injection of camphor, coincident with the disappearance of dyspnea and cyanosis. In general the pressure is above normal in all cases of respiratory or circulatory embarrassment, but the chief value of the method lies in the fact that it may be the first symptom. The patient should be in the sitting posture with the sternum as nearly perpendicular as possible. Excepting well-nourished children, some veins sufficiently prominent can generally be found along the back of the hand or the radial side of the forearm. Cold interferes with the phenomenon and calcareous vessels should be avoided since they do not collapse readily; and good light is essential, the patient's respirations should be free and easy and the arm should be horizontal, with muscles relaxed.

HISTOLOGY, PATHOLOGY AND BACTERIOLOGY.

Relationship of Duodenal Ulcer to Acute Eczema.—The relationship of burns to this form of ulceration is well known, also the effect of the modern antiseptic treatment of burns in reducing the frequency of duodenal ulcer is generally recognized. HUGH H. BORLAND (Lancet, Oct. 17, 1903) relates the following history of an eight months old baby, who succumbed to this most unique condition. The child was breast-fed until the seventh month. Very early he began to suffer from eczema of the head, which persisted. He was vaccinated at the fifth month. At the sixth month the face became eczematous. Submaxillary gland swelled and appeared to be suppurating. This subsided, however. At the eighth month there was an exacerbation of the eczema which took on a virulent form, extending to the trunk. After this the temperature rapidly became subnormal and all the other characteristics of profound infection were present. The skin was so affected that it was abraded by the simple wiping away of the exudate. Later the eruption became pustular and discrete. He vomited some blood and from this time the motions were tarry. He had extreme pains in the abdomen; vomiting was marked. These characteristic symptoms of ulcer persisted until the child died of hemorrhage. The pathological report showed no evidence of peritonitis. In the lesser sac was a clot practically filling it. A round ulcer on the posterior wall of the duodenum just beyond the pylorus had perforated, the opening being about the size of a split pea, and directed toward the lesser sac. The stomach was normal, although slightly congested. All other organs were normal. The skin of a child is relatively greater in area than that of an adult in its ratio to the body-weight. Hence cutaneous lesions in infants would be expected to produce correspondingly greater disturbances in the intestines. Whether this be due to impairment of the function of the skin, to nerve irritation, to destruction of red corpuscles or leucocytes or to absorption of toxins from the disintegration of the blood corpuscles is not known, although it is probable that the belief in a septic embolus being deposited in the walls of the stomach and so establishing a zone of lowered resistance is the most probable. As this is the first recorded case of ulceration following eczema nothing can be said as to the relative rates of appearance of the ulcer, which is known to give evidences of its presence in burns as early as from four to six days after the injury. It is probable that if the attention of practitioners had been called to these possible relationships, more literature might have been collected, because many cases have probably passed unrecognized.

Rôle of the Blood Fluids in Phagocytosis.—The experiments performed by A. E. WRIGHT and S. R. DOUGLAS (Proc. of the Royal Soc., October 31, 1903) show that the blood fluids play an important part in phagocytosis. They modify the bacteria in a manner which renders them a ready prey to the phagocytes. This is spoken of as an "opsonic" effect (*opsono—I cater for; I prepare victuals for*), and the authors employ the term "opsonins" to designate the elements in the blood fluids which produce this effect. The question as to whether the blood fluids contain, in addition to opsonins, also an element which directly stimulates the phagocytes, remains for the present unsolved. The opsonic power of the blood fluids disappear gradually on standing, even when the serum is kept in a sealed capsule sheltered from the light. The opsonic power of the serum is diminished when this last has been digested with typhoid bacteria. The opsonic power is diminished while the phagocytic power of the leucocytes is preserved when the blood fluids and corpuscles are separately digested with *Daboia* venom. This probably explains the reduced resistance which supervenes upon viper bites. The study of immunity must therefore include the phagocytic power of the white blood cells, the agglutinating, bacteriolytic and bactericidal powers of the blood-fluids and, lastly, the opsonic effect of the latter. As a concrete example is adduced the following: The condition of immunity to staphylococcus which can be induced in patients unduly susceptible to staphylococcus infections, by the inoculation of properly adjusted doses of a sterilized staphylococcus culture, is associated with an increase of the phagocytic power of the white blood corpuscles, and unaccompanied by any development of a bactericidal power in the blood fluids.

Pathology and Classification of Intussusceptions.—Intussusceptions may be classified into single, double, triple and so on, but inasmuch as the lesion is usually considered to be single, these classes are by no means universally employed. EDRED M. CORNER (Ann. of Surg., Nov., 1903) in a long analysis of this disorder, shows that double intussusceptions are of great frequency. He divides the single form into four varieties, viz., enteric, that is, of small bowel only; ileocolic, when small bowel is prolapsed into the ileocecal valve; ileocecal, when the

valve forms the leading part of the intussusceptum; colic, when only large bowel is implicated. By ileocolic is meant that invagination has begun in the ileum and then passed wholly or in part through the valve. He concludes, (1) that double intussusceptions are more common than single; (2) that ileocolic intussusceptions are the most common of all, colic-ileocecal next; (3) the single ileocecal variety is decidedly uncommon, found usually in chronic cases; (4) the ileocolic is the most common variety of primary intussusception; (5) the inversion begins laterally and most frequently in the last part of the ileum, which becomes engaged in the jaws of the ileocecal valve; (6) the so-called ileocecal form probably arose in the last half inch of the ilium or the caput-coli; (7) that both in man and animals the ileocecal valve is probably never primarily responsible for the trouble. His conclusions regarding intussusceptions associated with Meckel's diverticulum are that the two following groups exist: (*a*) when the process opens at the umbilicus as well as into the small intestine; (*b*) when it is only in connection with the intestine. This is the larger group.

Physiological Factors Which Govern the Temperature Range in Tuberculosis.—In studying the normal temperature curve of the monkey, J. J. GALBRAITH (Proc. Physiol. Soc., Jour. of Phsyiol., Nov. 2, 1903) finds that it closely corresponds in form with that found in simple tuberculosis in the human subject, there being an imperfect control manifesting itself in the form of an increased diurnal variation and a greater liability to disturbance of the form of the wave by variations in the external conditions. The author studied the behavior of the wave in the tuberculous monkey, with the view of ascertaining whether the temperature swing in human tuberculosis is not capable of a physiological explanation. The temperature curve in the tuberculous monkey shows the following features: (1) An increased amplitude of the wave as compared with the average; (2) the mean daily temperature remains practically unaltered, the exaggeration taking place in the downward as well as in the upward direction; (3) the swing follows exactly, as in the normal animal, the curve of metabolic activity; (4) reversal, or modification of the direction consequent on reversal, of the metabolic phases, the tuberculous monkey reacting more rapidly than any of the others to the various experimental changes; (5) exaggeration of the accidental waves caused by excitement exercise. The conclusions deduced from the study of the curve (which are strongly supported by clinical evidence and study of the tuberculous swing in man) are: (*a*) That the character of the wave in the tuberculous monkey shows a further exaggeration of the deficient control which characterizes the normal monkey as compared with man; (*b*) that the swinging temperature of simple tuberculosis is metabolic in origin, as opposed to toxic, and can be explained by physiological laws; (*c*) that a constant rise of the mean temperature takes place, associated with secondary pathological changes.

Influence of Fever on Adrenalin Glycosuria.—Since the sugar sometimes disappears in diabetes when some febrile disease supervenes, the effects of artificial fever, such as is caused by injury to the corpus striatum, upon glycosuria, presents an interesting problem, especially since lesions of the "sugar center" in the fourth ventricle often causes a fall of temperature. E. ARONSOHN (Virchow's Archiv, Vol. 174, No. 2) first studied the effects of adrenalin alone. Subcutaneous injections of 0.01 gram to 1.5 kilogram body-weight, regularly, cause an excretion of sugar varying from 0.5 to 5.5 per cent. Intravenous injections are still more effective, but sufficient absorption from the mucous membranes does not take place. The sugar can be detected very soon; thirty minutes after injection 3.6 per cent. could be obtained and the amount was generally highest in four to six hours. A second injection does not materially increase the amount. Acetone was found in only one case, albumin in none. The effects of adrenalin never last longer than twenty-four hours, since the fall is equally as rapid as the rise. The condition of the temperature is variable; there is often a slight fever with commercial products but a subnormal temperature if fresh extract is used. The same injections were repeated with animals whose heat-centers had been injured and in no case was sugar detected in the urine. This interesting observation is best explained by the increased metabolism which goes on in the muscles during fever; this stimulus is probably sufficient to burn up the sugar which otherwise would be lost. If glycosuria is complicated by severe organic disease this peculiar action may be absent.

PHYSIOLOGY.

Resistance of Serum Proteids to Tryptic Digestion.—The interesting fact that a considerable portion of the proteids contained in blood serum preserves for a long time its coagulation in the presence of trypsin, is revealed by the researches of C. OPPENHEIMER and H. AUN (Beiträge z. Chem., Physiol. und Pathol., Sept., 1903). A preliminary coagulation destroys this property, which may also be considerably weakened by the addition of a small quantity of pepsin-hydrochloric acid. This resistance cannot be adequately explained by the hypothesis of the presence of an antitrypsin, but rather upon the basis of the existence of a specific configuration of the serum molecules, that furnish insufficient points of attack for the molecules of the ferment.

Laking of Red Blood Cells.—The interesting question presented itself to H. KOEPPE (Pflüger's Archiv, Sept. 11, 1903), namely, whether the laking of blood, the melting away of the red blood cells, the issue of hemoglobin from the latter, hemocytolysis, hemolysis—whether all these are the various expressions for one and the same process. Do all substances that destroy red blood cells, do hemolysins, globulicides, hematic toxins, act in the same or different ways? To answer this question the author performed a long series of experiments with the following results: Red blood cells are laked or lose their hemoglobin under the influence of (1) water, (2) heat, (3) hydrogen ions, (4) hydroxyl ions, and (5) a series of substances that dissolve fats. The laking brought about by water is attributed to the extraordinary difference between the osmotic pressures within and without the cells, which brings about a disturbance of the semipermeable wall. The laking produced by ether, chloroform, alcohol, acetone, etc., which are all capable of dissolving fats, suggests the hypothesis that the semipermeable wall of the red blood cell consists of or contains a fatty compound. The action of heat in causing hemolysis would be explained on this basis, for heat would dissolve the fatty wall of the cells. The relative constancy of the temperature at which laking takes place would go hand in hand with the constancy of the melting-point of fats. To explain the laking action of hydrogen and hydroxyl ions, the author supposes that the former hasten the splitting of an ester in thin watery solution into the corresponding alcohol and acid, a process known as catalysis; while the hydroxyl ions bring about saponification of the ester. All the above agencies destroy the capacity of the cellular wall to be semipermeable, and as a result the hemoglobin is dissolved out.

Elimination of Apomorphine by the Stomach.—The following conclusions were drawn from a series of investigations pursued by A. VALENTI (Arch. Ital. de

Biologie, Sept. 10, 1903): Apomorphine introduced into the organism by hypodermatic injection is not found in the material vomited immediately after the injection, nor in the liquid obtained by lavage of the stomach, performed from one-half to six hours after the administration of the drug. This indicates that the emetic action of apomorphine resulting from stimulation of the spinal centers, is not re-enforced by a local action upon the wall and ganglia of the stomach. Since the apomorphine after absorption is not found as such in the gastro-intestinal canal, nor in the urine, it must undergo certain structural modifications within the organism. The production of the special antiperistaltic movements, observed by Schütz in the stomachs removed from animals to which apomorphine had been administered hypodermatically, can be attributed only to the final decomposition products of the base, which stimulate directly the muscular and automatic nervous elements of the stomach.

Pathogenesis of Epilepsy.—In a case where epilepsy had proved fatal, D. CREITE (Münch. med. Woch., Oct. 13, 1903) found the cortex of the brain the seat of a number of cavernous angiomata, the largest of which were surrounded by calcified connective tissue. They were probably congenital since the epileptic seizures began in earliest youth. Their relation to epilepsy can hardly be explained by variations in intracerebral blood-pressure since experimental venous stasis, even in epileptics, never brings about an attack and since compression of the carotids in animals, is never followed by convulsions. It is more probable that they irritate the cortex by their constant growth. Angiomata of the brain are rather rare, but have been found in several previously reported cases of epilepsy.

Copper in Syphilis.—There is a cachexia or condition of bad health which is not infrequently shown by old syphilities, in which there are no focal lesions, and which is manifested by weakness. Arteritis, with its manifold symptomatology and the various spinal degenerations which frequently result from late syphilis, are perhaps the most unsatisfactory manifestations of the disease to treat. A. F. PRICE (Med. Rec., Oct. 10, 1903), who is medical director in the navy, has found that copper exerts a much more beneficial influence over these conditions than either mercury or the iodides. He points out the fact that those cases manifest a peculiar susceptibility to copper, and he knows of no other disease in which this sensitiveness to copper exists. He has tablets of copper arsenite, gr. $^1/_{3200}$, which sometimes cause symptoms of prostration and collapse, even when given in dosage of only one per day. Great care must be taken at first till a tolerance is produced, and the drug should be frequently stopped for a few days. It is, therefore, a valuable diagnostic aid. After a dose of $^1/_{800}$ gr. is reached the copper sulphate is usually given made up in pill form, with gentian. In acute syphilis the sulphate may be given in doses of gr. $^1/_{20}$ from the beginning, combined with mercury. He firmly believes that copper has a very helpful action, and may greatly improve early cases of tabes.

Is Pharmacologic Action Determined by Chemical Structure or by Physical Characters? Many interesting examples are brought forth by A. R. CUSHNY (Jour. Amer. Med. Ass'n, Nov. 21, 1903), which show that the actions of various drugs are to be attributed more to the physical characters of the entire molecule than to any chemical reactions or combinations of the constituent groups of the molecule. It has been held, on a comparison of the effects of methane (CH_4), which is practically inert, and of methyl alcohol (CH_3OH), which is a depressant to the central nervous system, that the activity of the latter is to be attributed to the presence of the OH, which may combine with the protoplasm in the same way as with an acid. But, on the other hand, the alcohol may possess some physical property, such as a lower volatility, which endows it with some power to effect certain changes in the cells without any chemical reaction taking place. In support of the latter hypothesis the experiments of Kionka are cited. This investigator found that whilst methane (CH_4) is devoid of narcotic action, CH_3Cl has some effect. The presence of Cl appears to endow the molecule with activity; $CHCl_3$ is four times more powerful than CH_2Cl; but CCl_4, instead of being still more powerful, is only half as depressant as $CHCl_3$. This result suggests that the depressant qualities of this series are not determined by their molecular structure, but by some physical character which is present in a large proportion of the chemical group, but not in all of them. Hans Meyer ascribes the depressant action of this group to their tendency to pass from watery solutions into fats and oils. Other examples that lend weight to the physical theory of pharmacolical action are the following: It has been found by Sternberg in comparing bitter and sweet tasting substances that the hydrocarbons are practically indifferent, but taste is conferred on them by the introduction of two or more OH groups, when the sense of sweetness follows. Fisher's studies, on the optical isomers, have shown that the yeast cells, yeast ferments and emulsin can differentiate between the dextrorotatory and levorotatory isomeric sugars, while no ordinary chemical reagents select the one in preference to the other. The author has proved that levo-hyoscyamine acts 12 times as strongly in the salivary glands as dextro-hyoscyamine, although these two bodies cannot be differentiated by ordinary chemical methods. The activity of the hemolysin, saponin, appears to be determined by the solubility coefficient to its power of chemical combination. Certain drugs act only in the presence of other bodies, which are practically inert, but which tend to facilitate the solution of the active principles. For example, the active principles of the vegetable cathartics are often less satisfactory when given in a pure form than when mixed with the inert bodies with which they are found in nature.

GENITO-URINARY AND SKIN DISEASES.

X-ray in Circumscribed Peri-urethral Gonorrhea.—The utility of the X-ray as a diagnostic agent in urology is well recognized. Therapeutically, however, in the diseases common to this special branch of medicine, they have made but limited progress. R. KAUFMANN (Centralbl. f. d. Krankh. der Harn und Sex. Organe, Oct. 24, 1903) describes the technic made at Frankfort in three cases of peri-urethral infiltration. The intensity of the current was three to four ampères. The tubes were No. 3 and moderately hard. The exposure period was ten to fifteen minutes. In the first exposure a piece of sheet lead was used to shut off the parts intended to be protected. Later, however, a lead cylinder was used. The distance from the tube varied from 10 to 20 c.c. Three cases are detailed in full. They were each of cavernous infiltration which had resisted ordinary forms of treatment. The author does not claim that the rays are a panacea in the treatment of this condition or even that they destroy the bacterial life. It is apparent that they are a very decided factor for good, however they may work, whether by direct destruction of the bacteria or by causing the absorption of the inflammatory tissues. Three cases are not sufficient upon which to base any conclusions, but it would appear that the disorder is sufficiently superficial to lend itself favorably to this form of therapy.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

No. 111 FIFTH AVENUE (corner of 18th St.), NEW YORK.

SATURDAY, JANUARY 9, 1904.

PHYSICIANS AS HEADS OF MUNICIPAL DEPARTMENTS.

Two years ago, when the recently defeated fusion candidates were about to take office in New York City, the MEDICAL NEWS suggested the advisability of the appointment of a physician as the head of the Health Department. There had been previously a prejudice against the occupation of this position by a regular practitioner of medicine. This prejudice had actually been incorporated into the old charter of New York, so that a physician by a curious anomaly and inexplicable contradiction could not be given the charge of the health of the city of New York. Our suggestion of two years ago did not bear fruit, though it is our pleasure to say that the gentleman who was appointed to fill the position of Health Commissioner, a doctor of another faculty, wisely fulfilled the duties of the difficult office in a manner to deserve all praise. The demonstration of his success in office is to be seen in the lower death rate, which makes the city of New York at the present time almost as healthy as many of the so-called health resorts of the world.

While the present Mayor had the new appointments under consideration, we called attention to the fact that one of the best managed departments of the city government, during the fusion administration, had been that of the Street-Cleaning Department, at the head of which was a physician. Dr. Woodbury's success in this trying post has been the best possible proof that a physician could have the executive and managerial ability to control and coordinate the large number of assistants required for so important a department. This was in contradiction of the old cry that had formed the basis of the prejudice against physicians as heads of departments that they were likely to be lacking in administrative capacity. The condition of our streets for two years and the number of improvements introduced into the Street-Cleaning Department, have undoubtedly marked the administration of the first physician appointment as one of the most noteworthy in the history of the city.

While the lowered death rate must be mainly attributed to the well-directed activity of the Board of Health, there can be no doubt that the fact that a physician was in charge of the Street-Cleaning Department was no insignificant factor in the production of this very favorable result. These two city departments can be coordinated in many ways with decided advantage to the city's health. Cleanliness in the modern sense is not merely the removal of malodorous material nor the carting off of filth and refuse in order that it may not offend the eye or the nose. True cleanliness has become a study in bacteriology and any one who hopes to succeed in making clean streets that will at the same time be healthful must realize how much bacteria mean in the production of ill health and what important precautions are needed that micro-organisms may not be allowed to infect food products, nor, as far as possible, be blown about, thus finding an entrance into the houses in crowded districts. It was this particularly that the physician Commissioner, who has to our minds so fortunately been allowed to hold over, accomplished to a greater degree than others, because of his special knowledge in these subjects.

We have no doubt that the new Commissioner of the Health Department, Dr. Thomas Darlington, will prove as excellent an example of the administrative capacity of physicians as has the brother member of the profession in the Street-Cleaning Department. Certainly it would seem that the new administration is giving many evidences of its earnest effort and sincere desire to secure the proper management of important departments of the city government. These two

appointments are such as must commend themselves to every one who has any knowledge of the conditions and who knows the men who are thus honored by the new Mayor.

These men will need the active cooperation of physicians all over the city to accomplish the sanitary results that may rightfully be expected of them. This should undoubtedly be given them to the best of professional ability. The percentage of deaths for the past year, recently reported in New York, was only a little over eighteen for each thousand of the population. That for the previous year, 1902, which was the lowest recorded up to that time, was much nearer nineteen per thousand. There is no doubt that these figures can be reduced still lower, and thus many thousands of lives be saved each year. A reduction of even one per thousand in the death rate means over three thousand less deaths than fore. The value of so many lives can scarcely be estimated, though it serves to give some idea of the economic value of the application of the great principles of sanitation and hygiene to the problems of administration in great city departments. There is every reason for hope that the prospect, which seems so bright, will be amply fulfilled.

PRESENT STATUS OF APPENDICITIS.

The discussion on appendicitis, at one of the meetings of the Harvard Medical Society of New York City, last year, did not bring out many new points in the diagnosis and treatment of this important affection, but it did show the present status of surgical and medical thought with regard to the most interesting of modern diseases. There is now a general agreement that it is practically impossible to diagnose appendicitis itself, that is, as a simple inflammation of the appendix without any involvement of surrounding tissues. What is really diagnosed is always the peritonitis which begins to develop as soon as all the coats of the appendix have become affected by the inflammatory disturbance within that little organ. The recognition of this state of affairs may seem to be of no practical importance and to represent only a change of nomenclature. As a matter of fact, however, it will make appendicitis much more significant and cause the practitioners of medicine generally to be more careful in any attempt to treat severe phases of the malady by medical means alone, if they appreciate that the inflammation at the time, even when the first sign occurs, is already outside the intestines in the peritoneal cavity, and consequently beyond all hope of direct influence from medication within the intestinal canal.

It is probable that there are certain mild attacks of colic, heretofore considered of very little importance, frequently occurring in children and looked upon as trivial results of indiscretions in diet, which are really little attacks of true appendicitis, that is to say, of a spasm of the mucous canal and the muscular coat of the appendix as a consequence of beginning inflammation in the mucous lining. One physician described a series of attacks that had occurred in one of his own children, in which there was simple colic with no rise of pulse and temperature but with a tendency for the attacks eventually to recur at shorter and shorter intervals. Operation in this case disclosed the presence of a grape-seed within the appendix, and beginning inflammation of the mucous lining.

It has been recognized for a good while now that the conditions found in the appendix at operations in adult life are often significant of very old pathological changes. Strictures of the appendix after all are structurally not unlike strictures of the urethra. It is well known that urethral strictures take many years—at least five to twenty—to form. It would not be too much to expect that corresponding changes in the mucous membrane and submucous tissue of the appendix would take at least as long to form. As a matter of fact, the blood supply to the urethra being quite abundant while that to the appendix is limited, it might reasonably be expected that the changes in the urethra would be considerably more rapid than those in the appendix, yet appendiceal strictures are often quite tight and distinctly indurated.

Apparently all, even the mildest form of colic localized in the lower part of the abdomen is much more likely to be appendicitis than anything else. The distinction between appendicitis and oophoritis or salpingitis, is often impossible, but the appendix must always be the first thought. Occasionally a diverticulum of the intestine may cause symptoms so like those of appendicitis as to be impossible of differentiation, but as this condition also requires operation under the circumstances, the error of diagnosis amounts practically to nothing.

One important fact, brought out in the discussion before the Harvard Medical Society, is that

many surgeons now consider it advisable to remove even the healthy appendix, if the abdomen is opened for some other reason. When this practice was first begun, it was looked upon as a bit of meddlesome surgery. Now even the most conservative surgeons are coming around to the idea, that it is sure not to do harm and absolutely precludes all possibility of the appendix ever being the seat of a serious pathological condition that would require the abdomen to be opened once more. Physicians themselves, when operated upon intra-abdominally, find it rather easy to grant the permission to perform this additional operative procedure, and this after all is the best possible index of the true conservatism of this practice. Future generations will probably know whether the habitual performance of appendectomy in all laparotomies will, by a process of organic modification with transmission of acquired characters, eventually lead to the development of the fortunately evoluted being—an appendixless man.

There is practically universal agreement now that while the surgeon and the physician and the patient's friends may regret delay in operation for appendicitis, it rarely happens that there is regret for an early operation. The disease is now known to be so treacherous that no one can foretell its course in any given case. Gangrenous appendicitis may, after a stormy beginning, give a remission during which the patient is apparently getting entirely well, when, as a matter of fact, death is becoming more and more inevitable. The insidious nature of gangrenous conditions in intestinal tissues was well illustrated in President McKinley's case. Some of the worst forms of appendicitis seem to run a course not unlike that of the late lamented President's, running a latent course until it is too late to save life, or, at most, do more than delay the fatal termination, since septic thrombosis of the mesenteric veins will surely lead to subsequent fatal complications. Fortunately, now it is not hard to secure permission for early operation, and in this lies the best and easiest method of cutting the Gordian knot of difficulties that so often surround appendicitis cases.

TWENTIETH CENTURY PROFESSORS.

THE musical query that delighted the audiences of the extravaganza of "1492"—"After the Fair is Over, What Will Chicago Do?" seems finally to have been answered by the recrudescence and production of a crop of "Specialists" and "Professors," that appears to be blessed with more than pernicious activity. This from an ethical standpoint, is bad enough, though when one reformer advocates the cult of a single meal a day, with a cloistered life behind closed doors, while another extols the fad of outdoor exercise, with frequent but reduced amounts of food, it does little harm, as the extremes, in these cases, seldom meet across the barrier of the exigencies of an active business career.

But when a man, like Dr. John Dill Robertson, who might popularly be supposed, by the laity, to be an authority in a learned profession, announces to the world, from the Auditorium at Chicago, that cleanliness is sitting at the right hand of disease rather than next to Godliness, and that it is not injurious (despite the traditional gilded youths of the Roman captives—the *jeunesse dorée* of the triumphant processions of Nero) to choke the pores of the skin with dirt and sudorific accumulations, it is time to cry a halt.

The gospel, according to this latter-day prophet, is explicit, if it is nothing else. "When people leave off bathing, there will be little or nothing for the doctors to do. Pneumonia, colds, and a hundred other ills, result from the foolish habit of washing the body. To bathe is to be dirty, for you thereby make a sewer of the skin. Blood attracted by the skin, gives up products that should be left to seek a natural outlet, and soils the skin." Later on, he goes farther afield and after saying that the theory that the closing of the pores of the skin would result in death is false, denounces in no measured terms, the habit of taking what he terms "dry baths." For he says "the rubbing of a rough towel over the skin removes the natural scales from the 'false skin' and conduces to the growth of bacteria on the skin."

All this will doubtless seem attractive to certain classes, in any community. As a nation we are to a degree still young to the importance of constant ablutions; a sense of which has been carried to such an extent by our English cousins —and we are now only beginning to emerge from the Saturday night tub epoch, and becoming habituated to the daily bath habit. Weary Willie and Plodding Pete have not yet included folding bath tubs in their traveling impedimenta, and will welcome converts to their fixed habits, while the schoolboy will be at last induced to believe that he has found something seductive in modern science.

The worst of it, too, is the singularly opportune time that the "professor" of these heresies has

taken to profess. Many a scheme that would have failed on account of its folly has been aided and has acquired headway from some fortuitous outside circumstance, and the cold weather that has been so prevalent of late, only adds to the ease with which a bath is dispensed with. Had Dr. Robertson launched his crusade in the hot summer months, when cold water was a necessity and not a luxury, the raucous echoes of his diatribe would hardly have reverberated beyond the walls of the Auditorium.

As to the facts from which he draws his deductions, and the statistics from which he reaches his conclusions, they all depend on a *single* Eskimo, who was deported from Greenland, and after being washed, died of pneumonia at Boston. One case, however, is hardly enough to prove the habits of the civilized world at fault, even to the satisfaction of a Chicago jury and there is no more reason to believe that one Eskimo will constitute a winter, any more than that one swallow will make a summer. Anyone, moreover, who has seen a Greenlander in his native habitat, can easily understand that the removal of his grease-stained, oil-impregnated, blubber-saturated epidermis would leave him in a condition to acquire any form of sudden death that might be lurking in his immediate neighborhood. Even here, however, we are inclined to attribute his death more to a change in his raiment than to the unaccustomed effects of soap and water. Several years ago, a band of Sioux chiefs, that had come on a mission to Washington, were allowed, in exchange for some lands, to choose whatever was nearest to their aboriginal desires. They promptly selected a sectional wooden house, a cylindrical stove, broad-cloth clothes, silk hats and hobnailed shoes. On their return, the house was built, the fire was started, and for several days the air was redolent of burnt leather and singed woolen, in combination with goat-like and other Indian smells. Finally hunger became imperative, and they were forced out of doors in search of game. The clothes, however, with the hats and shoes, were left by the fire, and the braves took to the trail in the scandalous costume of the Greek slave—modesty only being assuaged by the habitual breech-clout and the customary feather. That they all died from pneumonia is true, but there was no record of any concomitant cause of death from bathing and there is no more cause to attribute it as one in the case of the Icelander.

As Balzac remarked, there is nothing in the world that resembles a pussy cat so much as another pussy cat, so there is nothing in the world of animate creation that is as dirty as a dirty Indian, unless it is another filthy savage, or a *clean* Eskimo. Nevertheless Indians do use baths in sickness, but as they resume the coverings to which they are accustomed, the deaths can usually be accredited to the disease for which they took the baths rather than to the baths themselves. An Eskimo's clothes are not only fearfully and wonderfully made, but are alive with interest and—other things. They are fashioned from incompletely cured skins, are very heavy, and like the mink coat of Cetawayo, are "possessed of a very fine odor when wet." Deprive a native of these, and then turn him loose to the east wind of Boston, and the result will be fairly certain, no matter whether "he is to bathe in fiery floods, or to reside in thrilling regions of thick ribbed ice."

With regard to the "Professor," take him all in all—his published reports and his utterances—we presume that he is a medical man, but we most sincerely trust that we shall not see his like again. In the first place we do not believe that he practices what he preaches, but rather that his sole desire is to bathe in the turbid waves of the notoriety that his statements have evoked, and that he seeks merely to apply the golden ointment, derived from his advertising, to the itching palms of his medicinally dirty, and ethically unwashed hands.

The birth rate of Chicago is large, and more than one fool is born in every hour. Wisdom, too, is not confined to babes and sucklings, and this enterprising "specialist-surgeon" doubtless sees a large and extending clientele among the credulous and ignorant masses of the community. As James Russell Lowell might have said

John D—
Robertson, he
Said, they didn't know everything down in Judee.

ECHOES AND NEWS.

NEW YORK.

Fiftieth Anniversary of the New York Infirmary for Women and Children.—A meeting to celebrate the fiftieth anniversary of the New York Infirmary for Women and Children will be held at the Waldorf on Saturday, January 16, at a quarter past eight o'clock. Addresses will be given by Dr. William H. Welch, of Johns Hopkins University, Miss M. Cary Thomas, President of Bryn Mawr College, Dr. Emily Blackwell and Dr. Annie S. Daniels.

Dr. Macy to Be Transferred.—It has just become

known that the State Commission in Lunacy has voted to transfer Dr. William A. Macy, superintendent of the Willard State Hospital, to the Kings Park branch of the Long Island State Hospital, Dr. R. M. Elliott of the Flatbush branch of the Long Island State Hospital to Dr. Macy's place at Willard hospital, and Dr. Oliver M. Dewing, now superintendent at the Kings Park branch, to Flatbush.

Suspension of Tuberculous Policemen.—At a recent meeting of the New York Health Department, which was attended by President Lederle and Commissioner Doty, a resolution was passed to the effect that no member of the Police or Fire Department shall be permitted to remain on duty when found to be suffering from tuberculosis in its infectious stage. That action was taken on the report of Dr. E. T. E. Marsh, chief surgeon of the Police Department, that seventeen members of the department were suffering from the disease in a stage dangerous to their associates. It was explained by Dr. Lederle that, while this resolution might seem to work a hardship on the afflicted members of the forces, it is, in reality, in the interest of both the sufferers and their comrades. In this day, he said, the one chance of recovery which is left to the patient is given to him, while others are protected from possible infection.

The Mosquito Extermination Conference.—What is described as "The First General Convention to Consider the Questions Involved in Mosquito Extermination" was held in the rooms of the Board of Trade and Transportation, New York City, on the afternoon of December 16. A temporary organization was effected by electing Mr. Robert W. De Forest, Tenement House Commissioner of New York, as President; Mr. Henry Clay Weeks, of Bayside, New York City, as Secretary, and Wm. J. Matheson, described as "the father of the movement on the North Shore, L. I.," as Treasurer. After an opening address by Mr. Weeks, a paper sent in by Prof. John B. Smith, State Entomologist of New Jersey, who is located at Rutger's College, New Brunswick, was read. The paper was on "How a State Appropriation May Be Used," and described the work done during the past season under the direction of Professor Smith, and by the aid of the first State appropriation for mosquito work ever made in this country. During the past summer seven men were kept in the field, distributed well over the State. A total of 33 species of mosquitoes were collected, and 31 of these were bred. One or two more species may yet be found, but it is thought that the mosquito fauna of the State has been pretty fully covered. A small sum of money was spent in experimental ditching for drainage. Professor Smith considered it legitimate for a State to make mosquito surveys and to give general advice, leaving to local communities the work of extermination. Money should first of all be spent in study, so as to avoid the loss of public confidence which would follow mistaken executive measures. Mr. Walter C. Kerr, President of Westinghouse, Church, Kerr & Co., told "What a Rural Community Can Do." The community was on Staten Island, and included an area of some two square miles, embracing both marsh land and upland. In 1898 subscriptions were secured and 25 ponds were covered with petroleum oil. Later the ponds were drained. The oiling was temporarily, but the drainage was permanently effective. The greatest difficulty met was such marsh lands as could not be drained. Plans to exclude sea water from these by tide gates were under consideration when annexation to New York City checked the proposed municipal undertaking. Mr. Wm. N. Berkeley, M.D., of New York City, read a paper on "The Exactness of Proofs of Transmission of Malaria." Dr. E. Porter Felt, State Entomologist, Albany, N. Y., read a paper on "What New York State Ought to Do." He deemed it essential that practical work, particularly where undertaken on a large scale and when requiring many years' time, should be based on scientific principles. The needs in the vicinity of New York City are the greatest, for within a radius of 25 there are some 200 square miles of marsh land, about equally divided between New York and New Jersey. A biological survey of swamp and marsh areas, particularly near the large cities, is needed. The example of New Jersey might be followed and such work entered upon; perhaps in cooperation, so far as possible, with New Jersey. The problem could perhaps be studied sufficiently if there were available for four or five years an annual appropriation of $3,000 to $5,000. Mr. Weeks said mosquito extermination is essentially an engineering problem. Other features of the work are highly important, but the engineer may best determine and carry out plans to get rid of the breeding places, often involving the redemption of thousands of acres of marsh or saturated acres of vast value. Heretofore engineering has been for and not against the mosquito. Breeding places have almost universally been caused by engineering works. This applies to highway, railroad and landscape engineers. The result has often been the depopulation of valuable sections by malaria and its bearers, the *Anopheles*. The better term is "economic engineering," for the work covers a wide range besides simple extermination—the utilization of large areas for agriculture and even for habitation, and the improvement in living conditions of a vast population. During the conference a resolution was adopted providing for a committee of ten, to be named by the chair, to consider and report on permanent organization, the committee to have power to promote legislation, to arrange for the publication of the proceedings of the conference, and to call another conference whenever it should see fit.

A Highly Creditable Showing for New York.—The death rate for New York, says the *Sun*, for the last year, as calculated by the Health Department, is the lowest in the history of the records of mortality of this city. Up to the close of last week it was estimated at 18.15 in the 1,000 annually, as against 18.75 in 1902, and when the returns for the full year are in it is likely to be even less. Since 1890 there has been so great and steady a diminution in the percentage of mortality that it indicates a most creditable and most hopeful improvement in the health regulation, and also, and very significantly, in the cleansing of the streets. The death rate of Manhattan and The Bronx was as high as 26.31 in 1891. In 1898, taking in the whole city as now constituted, it had fallen to 20.26, in 1901 to 20, in 1902 to 18.74 and 1903 it has gone down to 18.15, according to the present calculation. New York, therefore, now takes its place among the healthiest cities of the world, yet in none other of them do the conditions unfavorable to health present a problem so difficult of treatment. Nowhere else is the crowding of population so great as in the densely populated districts of New York. In London, for example, only seven of the twenty-one subdivisions have more than 123 persons to the acre, while the thirty-four Assembly districts of Manhattan average

more than 131 persons. The densest London district, with 623 acres, contains only 200.6 persons to the acre. In New York the Eighth Assembly district contained in 1900 as many as 735.9 to the acre, and on 2,626 acres of the city there were more than 200 persons to the acre. About eight hundred thousand persons in New York are housed more densely than the 130,989 inhabitants of the most crowded London district. Moreover, the densest London district increased in population none at all or only slightly between 1891 and 1901, while the most congested part of New York, the lower East Side, increased its population between 1895 and 1900 at the rate of 10.6 per cent., and the most crowded district, the Eighth, by 6.7 per cent. This increase, too, has been going on steadily during the last three years. The densest London district has 11.5 persons to a dwelling, but in only two of the Assembly districts of Manhattan, the Twenty-fifth and the Twenty-seventh, is the average lower. Even in Brooklyn as a whole the average number of persons to a dwelling is nearly as large as in the most crowded dwellings of London. These facts suggest the vastly greater difficulty of the health problem in New York, and added to them is the volume of immigration steadily pouring into the most crowded districts here, while in London that stream is relatively insignificant. Here is a comparison of the present death rate of New York with that of the chief European cities in 1902: London, 17.7; Liverpool, 22.5; Paris, 18.4; Berlin, 18; Vienna, 19.4; St. Petersburg, 23; Rome, 20; New York, 18.15. Considering the peculiar social conditions in New York, this is a showing most creditable to our Health and Street-Cleaning Departments, and the more so because not many years since New York led the list with its high death rate.

PHILADELPHIA.

Result of Medical Examination.—At the recent winter meeting of the State Board of Medical Examiners but 57 out of 103 applicants were successful, the failures reaching 42.2 per cent. Four men were expelled for cheating and one withdrew. Members of the board stated that the large percentage of failures was due to the severe examination, which was made more difficult than ever before.

City Theaters to Be Inspected.—Because of the object lesson furnished by the recent Chicago disaster, Mayor Weaver has determined upon a thorough special inspection of all the places of public amusement in Philadelphia. For this purpose he has appointed a committee of seven persons, including the fire marshal, the chiefs of the Bureaus of Fire, Building Inspection and Electricity, two prominent builders, and a civil engineer. This committee will begin their work at once to ascertain in what respects the public safety demands immediate improvement upon existing conditions.

Hospital at Butler to Be Discontinued.—The "Philadelphia" hospital at Butler, Pa., is to be closed on January 15. This has been decided by the Citizen's Permanent Relief Committee on the recommendation of Dr. M. S. French who has been in charge of the work there. It is believed that the typhoid epidemic has been conquered and that the hospital will not be needed after the time mentioned. Dr. French spoke most highly of the work of the 25 nurses sent from this city at the beginning of the epidemic. A committee was appointed to prepare a testimonial to be given to the physicians and nurses on their return.

Coroner's Statistics.—The work of the coroner for 1903 exceeded that of any other year in the history of the office. The number of inquests was 3,357—553 more than last year. There were 58 homicides, 202 suicides, 94 deaths by drowning and 932 casualties. Among the latter were 254 on steam and electric railways.

Affiliated Scientific Societies.—The meeting in this city December 29 and 30 of the affiliated American Scientific Societies was a successful one in every way, social as well as from a strictly scientific standpoint. Smokers, luncheons and receptions were tendered the visiting members whenever the scientific program permitted. The meetings were held in the buildings of the University of Pennsylvania except the second day's meeting of the American Physiological Society, which was held in the physiological laboratory of Jefferson Medical College. The first annual meeting of the American Society of Vertebrate Paleontologists was held in Biological hall, it being decided to affiliate this with the other societies.

A Case of Rhinophyma.—An interesting case of this rather rare condition, in which operation was followed by remarkably good results, was reported at the Philadelphia Academy of Surgery, January 4, by Dr. W. W. Keen. The patient was a man of sixty-five years, a tailor by occupation. There was no history of injury. Fifteen years ago he had what was probably an attack of acne rosacea in which the nose and the adjacent borders of the cheeks were most prominently affected. This was followed by a nodular growth of the nose which involved all of that organ except the upper fourth. The growth gave rise to no pain. Breathing was not interfered with, but the projecting mass caused much difficulty in eating. Operation consisted in an elliptical incision with removal of the enclosed part followed by shaving of the growth on each side. Contrary to expectation there was but very little hemorrhage. The cosmetic result is very good, an interesting point being that over the area where the growth was simply shaved off there has been reproduced normal appearing skin instead of scar tissue. Histological study of the removed tissue showed it to be a soft fibroma of the skin with conspicuous distension and possibly hyperplasia of the sebaceous glands.

Pathological Society of Philadelphia.—The Annual Exhibition Meeting of the Philadelphia Pathological Society will be held on Thursday evening, January 14, 1904, at 8 P.M. at the Mutter Museum of the College of Physicians. This exhibition includes extensive gross and microscopic exhibits embracing every department of human and animal pathology. Members of the medical profession are invited to attend.

CHICAGO.

Detention Hospital.—The total number of patients admitted to this hospital during the year was 1,491 and 1,465 of these were taken to various institutions. They were distributed as follows: To Dunning, 809; Elgin, 142; Kankakee, 172; Watertown, 3; Bartonville, 1. Three hundred and nineteen patients were discharged, 19 died, and 1 escaped. Number of patients remaining at the Detention Hospital, 26. Total number of patients received at both the County and Detention Hospitals was 23,718.

Hospital Building.—The total cost of the new buildings and alterations in old buildings was $109,932.09. Besides the hospital for contagious dis-

eases, at the County Hospital are the five cottages for tuberculosis patients and three new cottages for insane patients at Dunning. A Children's Hospital, to be built at the County Hospital and to cost about $75,000, is planned for the coming year.

County Hospital.—Many changes and improvements have been made and are under way. A new heating plant has been erected, an X-ray department installed, and a new building for the isolation of contagious diseases is now in the course of construction. The following work was accomplished at the County Hospital during the year 1903: Number of patients treated, 22,227; discharged, 19,430; died, 1,996, and remaining in the hospital, 801. The sum of money expended for supplies, improvements and repairs, $184,520.21. Expended for salaries, $128,400.63, making the total cost of maintenance, $312,920.84, with a daily cost of maintenance of $857.31, or about $1 a patient. Training school for nurses started and new rules have been adopted for the conducting of the institutions. New cottages for the insane and for consumptives are being constructed. Superintendent Podstata reports an average daily number of patients at the insane department of 1,750; poorhouse, 950; tuberculosis ward, 95. The annual appropriation of last year for supplies was $215,000, and was practically used up; for salaries, $141,000; $6,800 of this appropriation was unexpended. During the year Dr. John R. Nealy resigned and was succeeded by Dr. Podstata.

Pneumonia.—The total 139 deaths from pneumonia are the highest for any December week on record. They form 27 per cent. of the total mortality from all causes, while the 49 deaths from consumption are less than one-tenth the total deaths of the week.

Investigation of Cities by State Board of Health.—The State Board of Health has just finished a sanitary investigation of 75 cities of Illinois, the public water supply of which has been subjected to a careful chemical and bacteriological analysis. The water has been pronounced good in the greater number of cities. In those in which there was evidence of contamination of the water supply, the Board has consulted with the local authorities in the endeavor to discover the cause of the pollution and to suggest a remedy. Sanitary officers of the Board have been sent to the majority of cities for the purpose of investigating unsanitary conditions, and to advise the local authorities as to the steps necessary to prevent an outbreak of disease.

Report of City Health Department for the Year 1903.—Commissioner Arthur R. Reynolds, in his report, says that of the principal cities of the country Chicago has the lowest death rate and spends the least for health purposes. These assertions are based on the latest official reports of the United States Census Office, and the United States Department of Labor. Figures show Chicago's death rate to be 4.7 per cent. lower than the average of 12 other cities.

GENERAL.

Butler's Typhoid Spreading Down the River.—The scourge of typhoid that has Butler, Pa., in its grasp is creeping slowly down the Ohio. Pittsburg's announcement that the number of cases there has increased is followed by the discovery in Wheeling, where typhoid is always prevalent, that new cases are maturing rather more rapidly than before.

German Consumption Cures.—The German Central Committee for Tuberculosis publishes some interesting statistics concerning the results of the open-air treatment of consumptives. During the year 1902 12,187 tuberculous men and 4,302 tuberculous women were treated in open-air hospitals at the expense of the Imperial Workmen's Insurance Office. Of this number, 78 per cent. were so far healed that there is no prospect of the disease rendering them incapable of work. If those cases are deducted in which, after a fortnight's treatment, it was evident that no cure could be effected, the successful cases numbered 81 per cent. Figures published by the Imperial Statistical Office show that the death rate from tuberculosis in German towns of 15,000 and more inhabitants is steadily decreasing. The number per 10,000 who died of consumption in the five years ending in 1881 was 357.7; in 1886, 346.2; in 1891, 304.5; in 1896, 255.5, and in the five years ending 1901, 218.7.

Salicylic Acid Harmful.—The food tests at the Department of Agriculture, which have been going on for several months past, to test the effect of salicylic acid on human health, are reported to have brought out the general fact that salicylic acid seriously injures health.

Tropical Ulcer.—Dr. J. H. Wright, director of the pathological laboratory of the Massachusetts General Hospital, in this city, has announced the discovery that tropical ulcer, a peculiar skin affection common to tropical countries, is caused by a protozoon.

Millions for New Boston Hospital.—The will of the late Peter B. Brigham, of Boston, was sustained by a decision handed down by Justice Lebaron B. Colt, in the United States Circuit Court, on December 30, and the $5,000,000 involved will go toward founding the Brigham Hospital according to the wishes of the testator. The heirs at law contested this provision.

OBITUARY.

Dr. HAMILTON A. WEST, of Galveston, Texas, died December 30, at the home of his brother, Dr. James N. West, 71 West Forty-ninth street, after a brief illness. Dr. West was Secretary of the Board of Health in Galveston during the flood there and performed valuable service in attending to the sufferers. For many years he was Secretary of the State Medical Society of Texas. Up to six weeks ago Dr. West was in active practice. He came to this city for treatment, but all efforts to save his life proved of no avail. Dr. West was born in Russell's Cave, Ky., March 31, 1859. He was a descendant of Samuel West, a brother of an ex-Governor of South Carolina. He was graduated with the highest honors of his class in Louisville, Ky., where he took his degree of M.D. As a physician Dr. West prominently identified himself with the interests of the City of Galveston. He was a professor in the University of Texas, and it was largely due to his efforts that the medical department of that university was founded. He made a special study of typhoid, yellow, and dengue fevers, and helped to point out the distinctions in diagnosis of the two latter. In 1897 Dr. West reported a case of yellow fever in Galveston and brought upon himself the censure of many citizens, who thought the announcement would injure the city. But Dr. West's diagnosis was confirmed by an expert, sent there by the Government. It was Dr. West's contention that such an announcement was for the good of the State of Texas, and he was in favor of quarantining the city lest the disease should spread and there should be an epidemic. Dr. West is survived by a widow and

five children. One of his sons is in business in Galveston and another is at Princeton.

Dr. Anton Eidenbenz, a surgeon, who had practised in this city for over fifty years, died December 31 at St. Luke's Hospital of pneumonia. He was eighty-six years old. Dr. Eidenbenz was born in Hessel-Darmstadt, Germany. He was a surgeon in the Eleventh New York Regiment during the Civil War, and after his return from the army was for many years visiting surgeon of St. Luke's Hospital.

Dr. Silas J. Damon, a wealthy physician, formerly of Boston and Lowell, Mass., died last week at Bridgeport, Conn., aged fifty-eight years.

CORRESPONDENCE.

OUR LONDON LETTER.

(From Our Own Special Correspondent.)

London, December 12.

TROPICAL MEDICINE—CANCER RESEARCH—THE SECRETARYSHIP OF THE ROYAL SOCIETY—THE ANTIVIVISECTIONIST LIBEL ACTION.

The most notable event of the present week in our little world of medicine here is an address delivered by Sir Patrick Manson at the London School of Tropical Medicine. The occasion was a send-off to the Dean of the School, Sir Francis Lovell, an old medical officer of the Colonial Service, who, two or three years ago, made a very successful begging tour in the tropical regions of the British Empire, and who is about to start on a second mission with the same object. As the fruits of his first expedition he brought back $100,000. The School, which, within the last few months has been greatly enlarged, is now in debt to the amount of $50,000, and like the daughter of the horse leech it still cries "Give, Give." Manson, to whose impulse the institution of special teaching in tropical diseases is mainly due, recited the claims which the London School had already established on the support of the public. Since the School was opened in October, 1899, it has trained some 350 students, that is, graduates of medicine, who go there for special instruction in tropical disease. The number is steadily increasing, showing that the School fulfills a necessary function. In its wards and laboratories students have the opportunity of getting into actual touch with the raw material of tropical disease, the germs which cause them, and the pathological effects of those germs on the human body. Besides being competent to deal with the diseases they meet with in the tropics they are trained in the methods of research so that they are able to grapple with the pathological problems which they have an opportunity of studying. In this way a whole army of eager investigators has arisen within the last five or six years who are throwing light on the dark places of tropical pathology. Sir Patrick Manson went on to mention some of the most important discoveries made by workers in the School. Dr. Low, the present Superintendent, first proved in the laboratory of the School how the blood worm, which is the cause of a group of diseases of the elephantiasis type, gains access to the human body. He showed that at an early stage of its existence the worm is introduced, like the germ of malaria, by the proboscis of the mosquito—a discovery which indicates the means of preventing these diseases. Dr. Forde, a pupil of the School, discovered in the Gambia Colony the presence in the blood of man of a new parasite which was afterward recognized by Dr. Dutton of Liverpool as belonging to the *Trypanosomes*, a group of parasites responsible for many grave diseases in the lower animals. Dr. Aldo Castellani, another pupil of the School, demonstrated the association of the *Trypanosoma* with sleeping sickness. Only a fortnight before the date of the address had the final proof that the *Trypanosoma* was the cause of sleeping sickness been obtained. Last year a patient in whose blood it was conjectured that the parasite was present was admitted to the hospital attached to the School. Dr. Daniels, after long search, succeeded in finding the *Trypanosoma*. The patient left the hospital, but specimens of her blood were sent from time to time to the laboratory for examination. In October she developed symptoms of sleeping sickness, of which she died on November 25, two years and three months after receiving the infection through the bite of a species of tsetse fly, common in the place on the Upper Congo, where she had resided. Sleeping sickness is rapidly spreading not only in the Congo Free State, but in Uganda and elsewhere in Africa. Manson is confident that the discovery of its cause will lead to the discovery of means for its prevention. Manson held that the school from which these discoveries had come had more than justified its existence. A sum of $500,000 is needed to further the work of research, and he earnestly appealed to the public for the money on a frankly utilitarian basis; for any one of the discoveries mentioned, he said, was worth the sum named ten times over.

It remains to be seen whether the School will get the money. It is certainly doing splendid work and, thanks largely to the support which it received from the late "pushful" Secretary of State for the Colonies, Mr. Chamberlain, its light has not been hidden under a bushel. Thanks to the liberality of Sir Alfred Jones, the Liverpool School has plenty of money, but it has no pupils. Still it has done useful work by sending out expeditions to West Africa and elsewhere. What the London School wants is a "pious founder" as free-handed as Jones, but it is doubtful whether it will find one who like him sees in the patronage of scientific research a means of furthering commercial enterprise.

Another subject on which research is very active here at present is cancer. The parasitic theory which almost held the field some time ago is now falling into the background. Mr. Henry Morris, who is Senior Surgeon to the Middlesex Hospital, where opportunities of studying the disease in all its varieties are especially abundant, in a lecture delivered at the Royal College of Surgeons on December 9, declared that up to the present time the microbic theory had not advanced our knowledge of the cause of cancer one step. The truth is, he added, that for the last ten or fifteen years cancer research has been too exclusively directed to microbes and too little to cancer. He expressed a strong opinion in favor of Cohnheim's "tumor germ" theory, which he believes to be the most—indeed the only—probably correct theory of the origin of cancer, and the only hypothesis that explains all the known facts. This theory so far from justifying pessimistic views as to radical treatment or prevention, in Morris' opinion, warrants the hope of a positive cure being effected if the disease is removed quite early and completely. I understand that Dr. Bashford, the Director of the laboratories of the Cancer Research Fund, while keeping an open mind on the subject, also believes that the weight of evidence, as matters stand at present, is against the parasitic theory. In a paper read before the Royal Society by Messrs. Farmer, Moore and Walker, on December 10, a theory, based on the study of a number of fresh specimens, was put forward that the distinctive pathological feature is a special mode of cell division. If they are right, the old "cancer cell," which we used to be taught to regard as a myth, turns

out to be a solid fact. None of the three observers is a member of the medical profession, two of them are zoologists, while the third is a botanist, and they seem to have attacked the problem purely from the biological point of view. If Ray Lankester is right, this fact makes it all the more likely that they have hit on the truth. That eminent zoologist has often expressed his contempt for the mere pathologist, holding that in biology lies the key to the origin of disease. As a proof, he points to the brilliant work of Metchnikoff, who began his scientific career as a zoologist.

The mention of the Royal Society reminds one of what Sir Lucius O'Trigger would have called "a very pretty quarrel," which has been raging among the august beings who manage its affairs. Sir Michael Foster, who recently resigned his chair of physiology in the University of Cambridge, has since given up the post of Secretary to the Royal Society which he has held for many years. The position is one which gives the holder a very large measure of power in the British scientific world, for he is virtually the irresponsible arbiter of the fate of young scientific workers. He can push a man on, indefinitely retard the recognition of his work, or suppress him altogether. In the discharge of such a trust the Secretary of the Royal Society is naturally exposed to much criticism. Being human, he is likely to give effect to personal preferences or prejudices. The position of Secretary has for very many years been held by a representative of scientific medicine, and it was hoped that on Foster's resignation the succession would fall to Dr. Halliburton, Professor of Physiology in King's College, London, one of the foremost of the younger generation of scientific workers here. A circular was issued by many prominent Fellows of the Society in which it was pointed out that "The nature of the science to which he (Halliburton) has particularly applied himself, physiology, places him, as it did both the retiring secretary and his distinguished predecessors, Sharpey and Huxley, at a nodal point for the sciences of the biological group, to which the collateral studies of pathology and medicine are attached." They went on to say that it seems highly advisable "that for the secretaryship there should, on the present occasion, be chosen a Fellow specially cognizant of the great biological field comprised under medical science." Owing, however, it is said to the opposition of Foster, Halliburton was put aside and the choice of the governing body of the Society has fallen on the veteran geologist, Sir Archibald Geikie. The choice of the President and Council, as Count Smorltork said to Mr. Pickwick, "surprise by himself," but the fact that Geikie should have accepted the post is still more amazing. He is seventy years of age; whatever ambitions he may have cherished in early life have been amply satisfied and he has practically retired from the field of scientific work. The spectacle of such a man accepting a post which taxes all the energy of a man in the prime of life makes one ask *Que diable est-il aller faire dans cette galère?* One hears whispers of jealousy of the representatives of medical science in the heavenly souls of the Council of the Royal Society. It is possible, however, that the explanation of their choice of an old man is a compromise like that which is known to have not infrequently made conflicting parties in the Sacred College agree to place in the chair of St. Peter an old man who should fill it long enough to give them the chance of strengthening their forces for a fresh fight.

The verdict in the action recently brought by Dr. Bayliss, one of the professors of physiology in University College, London, for slander against Mr. Stephen Coleridge, Honorary Secretary of the National Antivivisection Society, has given great satisfaction not only to the medical profession, but to level-headed men of all classes. The press, with the exception of one or two unimportant papers, has strongly condemned Mr. Coleridge's methods. His charges were shown in court to be based on nothing more solid than the statements of two ladies, who, on inquiry, turned out to be the Secretaries of a Swedish Antivivisection Society. Yet these ladies, who had attended Dr. Bayliss' class, not as students, but as spies, and who had described what they fancied they saw, or wished to see, in a book which the Lord Chief Justice who tried the case characterized as "hysterical," were put forward by Mr. Coleridge, as independent witnesses. Their cross examination seriously damaged his case, and it was utterly ruined by his own evidence. This, which was reluctantly and evasively given, showed that he had accepted the statements of the Swedish ladies without taking the trouble to test them in any way whatever. He practically said that he would not believe a vivisector on oath, and he treated the reports of the Government inspectors and the statements of the Home Secretary in the House of Commons in the like cavalier fashion. Yet, when a statement appears that the damages and costs of the trial, amounting to some $22,500, are to be defrayed by the Society which he represents, his solicitor gravely writes to the papers to say that the balance sheet to be published in the annual report will show that none of the funds have been used for the purpose. Apparently, therefore, Mr. Coleridge while refusing to accept statements of responsible officials and Ministers of State which do not suit his purpose, expects that the reports of his Society will be accepted as gospel truth. The trial will not stop the fanatical agitation of the antivivisectionists, but it may be hoped that it has taught them the salutary lesson that they must use a certain measure of discretion in their systematic lying.

LEUCOCYTOSIS IN APPENDICITIS.

To the Editor of the MEDICAL NEWS:

DEAR SIR: Allow me to make a most respectful but earnest criticism of the discussion on appendicitis, reported in your issue of Dec. 26, 1903, with particular reference to the remarks of Dr. George Brewer on leucocytosis. Dr. Brewer is certainly right in stating the fact that there is general disappointment regarding the results of blood examinations in appendix cases. But this disappointment is due to an attitude on the part of the profession, and, especially, of operators, which is not justified when we consider that leucocytosis is not an essential part of the septic process, but a reaction on the part of certain cells of the body. The great trouble is that we are always looking for pathognomonic signs and specific drugs, although we ought to realize that this quest is not much more reasonable than that of Ponce de Leon. Like Ponce de Leon, too, we fail to realize the value of what we discover, unless it fulfills our desire for the miraculous.

Leucocytosis is like accelerated pulse, high temperature, albuminuria, etc., of little value as pathognomonic evidence of anything and sometimes wanting when we think it ought to be present. I once had a consolidated pulmonary lobe without a particle of fever and one of my patients has recently manifested a pleuritic friction sound and other evidences of pleurisy, without rise of temperature, but I have not yet thrown away my thermometer.

The practical diagnostic point in appendicitis (why not say scolecitis?) is as to the necessity of operating, and operation in acute cases is indicated by two radically different processes, sepsis and necrosis. Either may

lead indirectly to the other, but they are, and in a rather literal sense, as different as life and death. Gangrene will not produce leucocytosis and sepsis will not if the resisting powers are too low. If we analyze this latter statement, it proves to be the crudest kind of a truism; if the body lacks reactive power, it will not react. But, in the great majority of cases, we can depend upon leucocytosis or its absence to indicate or contraindicate operation. Of course, the case should be studied carefully by a medical expert, not simply by a pathologist or an operator; and with regard to pulse, temperature, urine, local signs and general symptoms.

It seems that the reporter must have misunderstood Dr. Brewer in saying, "Very recently he has found that the differential leucocyte count seems to give important information. . . . the polynuclear leucocytes are increased much more than in their due proportion. Usually the polynuclears number about 62 per cent. of all the leucocytes. When over 70 per cent. . . . are present the surgeon may look for abundant pus formation." I have personally paid attention to this point for at least three years and it was not original or even unknown among hematologists at that time. But 70 per cent. of multinuclear (not polynuclear) cells are within normal limits, and no definite percentage can be assigned to suppuration. For instance, in normal blood we have about 5,000 to 8,000 leucocytes per cubic mm. Of these, ½ to 3 per cent. will be eosinophiles, 20 to 25 per cent. lymphocytes, and the remainder, about 75 per cent., will be multiformenuclears or polymorphokarytic cells. (Let us use either Latin or Greek, but not both in the same word.) If the so-called transition cells are excluded from the polymorphic cells, the percentage will be somewhat less, as Dr. Brewer states. As I understand it, any increase in leucocytes is on account of reaction to sepsis, consists almost entirely of polymorphokarytic cells. Thus, the percentage will increase according to ordinary arithmetic rules for mixture. For practical purposes, a leucocytosis that has to be counted to be appreciated, is not of great value, although an accurate series of counts showing significant increase or decrease, is of diagnostic and prognostic importance.

It would require too much time to go into the discussion of the relative merits of medical and surgical treatment. Suffice it to say that any such discussion implies the belief that promiscuous operation for symptoms pointing to some disturbance in the appendix is as illogical as similar recourse to surgery in other parts of the body.

Very truly yours,

A. L. Benedict.

SPECIAL ARTICLE.

BYWAYS OF MEDICAL LITERATURE.—XIX.

NON-EXERCISE AND LOSS OF FUNCTION.

In an article on Indifferentism in a recent number of the *Atlantic Monthly*, the editor, Mr. Bliss Perry, insists on the dangers of overspecialization with the consequent possibility of the loss through failure of function of a number of important intellectual faculties that would otherwise be a source of pleasure and perhaps even of profit. It is easy to understand after all that for lack of exercise many tastes and intellectual operations that would be at least important stimulating means of recreation, are lost through too close application to a few things. There are those who find in the present elective system of education this very danger. From his earliest serious years the student applies himself to something that he hopes will be of practical service to him later in life. His college course is only an introduction to his professional studies and gradually all his intellectual life comes to center around the narrow circle of his vocation in life. It is a warning to the young man commencing his studies, to the young physician entering upon his practical career and to the old physician who is often given the opportunity to advise others to realize the force of the example in this matter quoted by Mr. Perry:

"Here is a well-known passage from the autobiography of one of the most gentle, honest and unquestionably great men of our own day. It is the passage where Charles Darwin confesses his loss of interest in certain things which had once moved him deeply. The words are frequently commented upon as illustrating the atrophy of unused faculties. That is indeed their obvious purport, but as you read them, note how perfectly they echo, more than a century afterward the very tones of Signor Pococurante's confession in his library:

"'I have said that in one respect my mind has changed during the last twenty or thirty years. Up to the age of thirty, or beyond it, poetry of many kinds, such as the works of Milton, Gray, Byron, Wordsworth, Coleridge, and Shelley, gave me great pleasure, and even as a schoolboy I took great delight in Shakespeare, especially in the historical plays. I have also said that formerly pictures gave me considerable, and music very great delight. But now for many years I cannot endure to read a line of poetry. I have tried lately to read Shakespeare, and found it so intolerably dull that it nauseated me. I have also almost lost my taste for pictures or music. Music generally sets me thinking too energetically on what I have been at work on, instead of giving me pleasure. I retain some taste for fine scenery, but it does not cause me the exquisite delight which it formerly did. . . .

"'This curious and lamentable loss of the higher esthetic tastes is all the odder, as books on history, biography, and travels (independently of any scientific facts which they may contain), and essays on all sorts of subjects interest me as much as they ever did. My mind seems to have become a kind of machine for grinding general laws out of large collections of facts, but why this should have caused the atrophy of that part of the brain alone, on which the higher tastes depend, I cannot conceive. A man with a mind more highly organized or better constituted than mine would not, I suppose, have thus suffered; and if I had to live my life again, I would have made a rule to read some poetry and listen to some music at least once every week; for perhaps the parts of my brain now atrophied would thus have been kept active through use. The loss of these tastes is a loss of happiness, and may possibly be injurious to the intellect, and more probably to the moral character, by enfeebling the emotional part of our nature.'"

It is manifest that such atrophy of interests is not only a positive loss to the individual but is almost sure to impair the full significance of his life-work, since it narrows his point of view and makes him incapable of appreciating with entire correctness even his own chosen lines of thought. The only prophylaxis against this narrowing of intellect is a broad liberal education in the impressionable developmental period when the mind is susceptible to the acquisition of new interests and when these are likely to be permanent possessions if the habits they initiate become sufficiently part of the organism.

ANATOMY AND DISPOSITION.

In the course of some editorial discussion of that very interesting question: Shall the promise to obey on the part of the bride be omitted from the marriage

service? one of the religious weeklies, published in New York, gives the details of the change that has come over the meaning of the word buxom in the last couple of centuries. Some of the old marriage services have the expression and the woman shall be buxom to her husband; that is, shall be bowsome, in which the root to bow is obvious and the sense of obsequious, obedient, is clear. The nearest relative in a modern language is perhaps the German biegsam—flexible.

At the present time, however, buxom has come exclusively to have the meaning of vigorous, robust, with an added kind of largeness, breadth, sturdiness of body, and then the sense of cheerfulness, good temper. It is evident that somehow the realization has come into the mind of English humanity at least, that largeness of body is associated with submissiveness of disposition, that the woman ready to obey is more apt to be generous of proportion than otherwise. Hence has come the modern and now practically exclusive meaning of the word buxom. The change thus brought about enshrines the expression of the principle that Antony enunciates when he insists on his distrust of the lean and hungry Cassius in Shakespeare's Julius Cæsar. This tendency for students of human nature to find in the anatomical constitution an expression of the inner character is of course common at all times. It would be interesting to know whether the impressions thus conveyed are borne out by statistics. At the present time such words as ascetic are coming to have a physical rather than a spiritual sense, as if the influence of body on mind were more generally recognized than hitherto. The book recently written, "Why the Mind has a Body" is an exemplification at length of this newer state of feeling in these matters.

IBSEN AS A MENTAL NOSOLOGIST.

Those who are interested in Ibsen have been given an opportunity in New York and neighboring cities to see another excellent example of his supreme power of putting a disease entity upon the stage Of course it may be doubted how far the study of diseased conditions and their representation in dramatic form are a true subject for artistic effort, but then, as has been very clearly established by Kipling in his poem on the subject, it's clever and so forth, but is it art? This is a question that may be asked of many other things besides Ibsen's dramas. The latest production here in America, Hedda Gabler, is after all the simple straightforward story of a pregnancy psychosis. The heroine (save the mark)—let us say instead the principal female character—is an intensely selfish young woman before her marriage and all her selfishness and other undesirable qualities become intensified during the course of her pregnancy shortly after marriage.

Such a train of incidents, of course, is not an unusual occurrence in ordinary life. There is many a husband who dreads the recurrence of pregnancy because during its course life is so often made unbearable for him by the irritative nervous condition which develops in his wife. Of course, an opposite effect as the result of which the wife becomes especially solicitous and tender in her husband's regard during pregnancy is (the Lord be thanked), perhaps, even more frequent than the opposite condition, while the characters of most women are left practically unchanged.

Ibsen has taken an extreme example of the young woman eminently unlovable because of the self-centered concentration of her thoughts on herself at all times and has represented her character becoming absolutely malignant in its hatefulness under the influence of the pregnancy psychosis. As a result of this she tempts the man who has broken with the drink habit to return to liquor, and having obtained possession of the book that he wrote and which would probably serve to make his fame she deliberately burns it. Having brought disgrace upon him she provides him with the means of suicide and suggests it. He unfortunately, according to her idea, does not commit suicide in the esthetic manner in which she planned it for him, she proceeds to take her own life.

Needless to say these materials can be used in a very impressive and dramatic fashion. It is clearly, however, neither a study in manners nor in morals, but a study in neurology and nervous pathology. It seems too bad that the pitiful condition which develops in the young mother's mental state and which brings about all the extremity of the horrible denouements should be put upon the stage as if somehow it were a natural development out of a given environment. This is the fault with all of Ibsen's work that he deliberately selects some type of mental disease and puts it upon the stage. A century and a half ago it was the custom for London society people with nothing to do to go out to Bedlam, the insane asylum of the city and find amusement in watching the antics of the insane people. The idea of doing such a thing would be eminently repugnant to the present generation. As a matter of fact, however, the craving to see the plays that Ibsen writes is rooted in the same morbid new sensation-loving feeling which made the Londoners laugh at their insane. It has been pointed out some time ago that Ibsen's Ghosts is practically a study of paresis. Others of his dramas illustrate other phases of mental alienation. If the diseased condition were, as is the case with the introduction of Ophelia into Hamlet, only an incident in the course of the development of the plot then it might well find a place, since mental disease has a definite though very subsidiary place in actual life. But when the whole drama turns on the repugnant though wonderfully naturalistic description, it must be confessed of a type of nervous disease and nothing else, there can be no question of great art, since there is a pandering to the morbid side of human nature in order to produce effects and secure applause and interest by the very horror aroused.

A PHYSICIAN POET.

The present renewed interest in Gaelic literature has called attention once more to the career of a distinguished physician-poet very well known in Boston some twenty years ago and admired by all those who came in contact with him. One of the most interesting remnants of the old Gaelic literature is the story of Deirdre. Deirdre is the fair-haired Helen, of Irish mythical lore, the Princess of Ulster, on whose account it was prophesied before her birth by the old Druids that more blood would be shed than ever was shed in the land since the race began. "She will be fair, comely bright haired," as Lady Gregory put it in her recent version of Cuchulain "heroes will fight for her and kings go seeking her." "You will have a little grave apart to yourself; you will be a tale of wonder forever, Deirdre."

It was on this subject that Dr. Robert Dwyer Joyce, wrote his widely read poem of Deirdre, which was published by Roberts Brothers, of Boston, in their No Name Series in 1877, producing quite a literary sensation in the Boston of those days, as well as in other literary circles throughout the country. After the success of his poem had been widely proclaimed the author disclosed his identity. He was a practising physician of Boston and came of an ancient and distinguished Irish family. He had graduated as a physician at Trinity College, Dublin, and had practised for several

years in Cork before coming to this country in the early seventies.

A friend, Mr. Ormonde M. Reid, once asked him where he got the time in his busy professional life to write such a poem. He said that he had composed it on the street, in his study, anywhere and everywhere when his mind was not occupied with his profession.

Unfortunately only a few years after the publication of this poem his health gave way, the underlying condition in his illness evidently being tuberculosis, he returned to Ireland where, however, he did not long survive.

At the time of his death, the Boston papers published very flattering obituary notices and many of the magazines gave critical reviews of his literary work. It seems especially fortunate that the Gaelic movement has revived interest in the career and work of a man whose literary ability succeeded in making a place for him in English literature, even in the midst of the busy work which he had to accomplish in order to succeed in the task, ungrateful though it may be, yet absolutely necessary of doing, what John Hunter termed, "chasing the damned guinea."

NEUROSES IN FICTION.

Our modern fiction and playwriting has become so expressive of phases of neurotic feeling rather than of genuine traits of normal humanity, that even the literary critics are beginning to recognize that the neurosis is fashionable in fiction and that only those who are so morbidly introspective as to exhibit phases of feeling that are sedulously concealed, are commanding popular attention. In an article on Neurotic Symptoms in Recent Fiction, in the winter book number of the *Independent* of New York (Nov. 19, 1903), Mrs. L. H. Harris inveighs against this unfortunate tendency in our literature. She insists that sanity is the thing most to be desired. Sanity and a little dulness, for after all it is only the dull people who are quite sane. They do not know too much, and they do not feel too much, but they are safe. Their wits are not very keen, nor their spiritual altitudes very high, but they have an ethical quality that insures moral equilibrium. It is not good to be able to thank the Lord that we are not as other men, for the average of mankind is nearest to mental balance in present conditions when "half the world is off and the other half not quite on."

"In the first place, it will be observed that in novels of this class the neurotic condition is generally founded upon the sex element. Only a few authors venture to include the religious interest in this hectic demonstration of human passions. As a rule, a sickly yearning for the 'unutterable' takes the place of action and healthy aspiration in these books. In 'The Story of Mary McLane' we have an indecent exposure of an erotic temperament. Such types have always existed, of course; but the question is by what influence was the intelligence made to seize upon these secrets of a depraved nature and interpret them aloud? What is it in American life that gives courage for such a performance? We have too much enterprise in sensations. And in these feverish times we have made too free a use of our wits in the lower regions of existence, so that we are becoming too well informed as to what lies in our darkness. Formerly there was a simplicity in vice, an objectivity that evidenced and defined it, but this extension of mind into the nervous centers of passion has given a neurotic genius to its very weakness. It has added an accusation to consciousness and discovered to every reader of fiction the psychic regions of a new kind of criminality."

Mrs Harris points out that Southern writers from whom, according to temperament, most divagations in this matter might have been expected, are freest from them, showing that they are deliberate. She continues "And this is not inconsiderable praise when we reflect that in the North, East and West, wherever wit has been sharpened most by science, energy quickened by competitive ambitions, and intelligence deepened by study and meditation, we find a certain genius for revelation, a disposition to expose everything, from commercial facts to the nervous nakedness of the secret mind. Sexual perversity becomes philosophical and fascinating through a neurotic power of portrayal. Indeed, our scriptures of life are too much concerned with the underworld of passions, and our gospels are too much of wickedness—all of which is unfortunate when we remember how young we are, and how long we must hold out against the mania and wretchedness of that darkness which is before and behind us in prophecy and history."

There is no doubt that many morbid conditions are suggestively being emphasized, exaggerated and rendered inveterate by these pictures of pathological mental peculiarities. Just as the physical hypochondriac finds new symptoms in every medical discussion so the mentally disequilibrated find new fads in each problem novel that touch on all their own alienate ways.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

SECTION OF GENITO-URINARY SURGERY.

Stated Meeting, held November 18, 1903.

The President, John Van der Poel, M.D., in the Chair.

Instrument for Illumination of the Bladder.—Dr. F. Tilden Brown presented a useful instrument* (Fig. 1) for illuminating the bladder during suprapubic work. An electric light is passed through the urethra and controlled by an assistant, the cold lamp illumination being at the internal urethral orifice, thus having it most centrally placed as well as conserving room for the operative field. It could also be tucked in pockets within or about the bladder when passed through the suprapubic opening. The electric cord is to be sterilized by formaldehyde vapor and the metal part by boiling. In doing suprapubic prostatectomy, instead of working in the dark and by touch alone, this instrument† permitted one to see bleeding vessels which could be caught by forceps and subjected to torsion or ligature, thus the aspect of any such operation in the bladder is very materially changed. He also showed an arrangement of two specially right-angled catheters (Fig. 2) for suprapubic drainage; one leads from the bladder through the urethra, the other through the wound. These are fastened together at their lateral eyes before the operation, the one known as Carlton's catheter has its short arm of 3½ inches, a very suitable average length for the intravesical portion of a suprapubic drain. While Dr. Brown's catheter for the urethra has its short arm of three-quarters of an inch. Both have lateral, as well as terminal eyes. His scheme in using these conjoined catheters for suprapubic drainage, is, after the operation, but before partial closure of the suprapubic wound, to draw the distal end of the urethral catheter in retro-

* Before having this simpler illuminator made he had used for the same purpose the sheath of his composite cystoscope through which also the preliminary irrigation can be done as well as the air distention of the bladder to lift the peritoneum just before opening the former.

grade fashion from the bladder outward, then sometimes putting a safety pin through its wall just at the external meatus; while the method of removal after the suprapubic wound had all but closed is to take the safety pin

from the urethral catheter and draw upon the suprapubic catheter, bringing its lateral eye close to the mucosa; then inserting a pair of blunt pointed, but delicate, scissors, first using as a probe to feel the connecting thread before opening them to cut it. For a few days longer,

until closure of the wound, the urethral catheter is advantageously kept in place to prevent suprapubic leakage.

Dr. F. Tilden Brown said it was very important to avoid any operation solely upon the tuberculous bladder when one kidney or both were similarly diseased. He

F. Tilden Brown's Small, Sharp Curette for Ureter and Bladder.

believed it to be a waste of effort, and only harm could result when we gave the bladder an additional outlet while this viscus was mainly suffering from being fed with infected material from one or the other kidney. In answer to Dr. Le Fevre, Dr. Brown said that so far

Fig. 4.

F. Tilden Brown's Torsion Forceps.

as could be determined by a most careful examination in the case of the nephrectomy patient shown there were no other foci in the body. With regard to suprapubic cystotomy for tuberculous bladder lesions he said that the frequency with which permanent fistulæ followed these operations was due many times to carelessness in not anticipating the various conditions and possible complications. Consequently in not making proper provision by having at hand before the operation was begun the means to treat any such lesions actively and thoroughly either with the small sharp curette, galvano cautery, strong nitrate of silver solution or other known therapeutic measures, and then to close the bladder wound in layers providing only for a little drainage in the prevesical space. The unnecessary employment of water for distending the bladder previous to its opening was often responsible for pericystic infections. He believed it to be a fallacy to leave the suprapubic wound to take care of itself, to heal or remain open with the chance of becoming a source of great discomfort to the patient. In addition he believed the surgeon should be previously posted as to just what he was going to encounter by making a preliminary cystoscopic examination and then lay his plans for the sort of attack required as well as for the most appropriate subsequent drainage; this latter may be met by a somewhat continuous urethral drainage by retained catheter, or possibly perineal or vaginal. While in cases of advanced and extensive tuberculosis of the urinary tract with contracted bladder every care should be taken to maintain a most comfortable and permanent suprapubic drainage until the end. Large stiff tubes should be avoided. Dr. Brown said that two months ago he had occasion to remove a testicle which, from the physical signs, situation and clinical history, led him to presume it to be of cancerous nature. After removal and cutting into it he was still inclined to think the diagnosis correct. The pathologist reported, however, that it was tuberculous and involved the testis and not the epididymis.

Dr. John Van der Poel said he could vouch for the usefulness and practicability of the electric light shown by Dr. Brown, as it had been his good fortune to have used it in a bladder operation, when it gave a most excellent view of all parts of that organ, without in the slightest encroaching upon the space necessary for the operator. It seemed to fill a long felt want, and was much to be preferred to reflection from an electric light on the forehead.

Case of Nephrectomy for Renal Tuberculosis.—In connection with a short paper to follow, Dr. F. Tilden Brown showed a male patient, thirty-eight years of age, who, six years ago, came under his care suffering from frequent urination and severe right loin pains. The discomfort was so great that he was willing to have anything done for his relief. An examination of the urine showed the presence of tubercle bacilli, although scanty in number, and a turbid urine. It was necessary to learn positively which kidney was at fault if either, and to find out the condition of the other gland; therefore, the ureters were catheterized and the left kidney was found to be functionating normally, but the right was not, and its urine contained tubercle bacilli and leucocytes. Nephrectomy was advised and done at the Presbyterian Hospital when this quite unusual kidney* presented, where, instead of the ordinary necrotic or caseating foci, the surface revealed the appearances commonly seen in rather recent miliary tuberculosis and the interior was much of the same character. In addition there was a single cyst of walnut size at the lower pole. The patient was very stout and had had a previous operation performed for appendicitis some years before, which had left him with a somewhat protruding cicatrix at the place where an oblique lumbar incision would run into it. Hoping to avoid any hernial increase of this,

* Depicted in Reference Handbook of the Medical Sciences, Vol. 5, page 340.

as well as the bound down parietal peritoneum in the old scar, Dr. Brown made a vertical-longitudinal incision connected with a right-angled subcostal one; this enabled him to get at the kidney on stripping the parietal peritoneum forward. The kidney was removed with about an inch of the ureter; on account of the full abdomen and its thick walls, it was necessary to make a very generous incision. The patient has since been wholly free from pain, as well as evidences of urinary or other regional tuberculosis, so far as any demonstration of tubercle bacilli was concerned. Inoculations of the very scanty urine sediment in guinea-pigs had been carried on with negative results. It was interesting to note that the patient still has pollakiuria, not so marked as before, but yet unduly frequent, and this has been the main reason for the vain search for tubercle bacilli emanating perhaps from other parts of the tract. But no suspicion of a tuberculous focus can be raised, unless a very small but sensitive nodule in the prostate is of this nature. Therefore, it was concluded that his frequency in urination was the result of habit and also a somewhat previously contracted bladder, which is so often co-existent in this disease. At different times during the past six years, for short periods, he has been placed under dilatation treatment by intravesical irrigation with beneficial results. He is again under such treatment, and during a period of three weeks his vesical capacity has increased from two to six ounces, and his urinating intervals have proportionately increased.

Chronic Orchitis with Tuberculous Infection Simulating Sarcoma.—This was the title of Dr. John F. Erdmann's paper. This specimen was the right testicle removed from a physician about thirty-two years of age, who was seen on the third day of May of 1903. He stated that in 1899 while a student, taking notes, that in crossing the left thigh over the right he felt a sharp pain in the right testis as a result. That a slight epididymitis followed, but that later on the whole testicle swelled. This was about two months after the original injury. For the past year he noticed that it increased to about twice the normal size; that in the last six months it had begun to grow rapidly, having doubled its size of six months before. He had absolutely no specific, tuberculous or malignant history; never had had a gonorrhea. In the examination the testicle was found to be the size of a large goose egg, perfectly symmetrical, hard, no pain, sensitive only upon deep pressure. Examination of prostate and cord showed no enlargement, neither did the inguinal glands. The patient was placed upon anti-syphilitic treatment for a time; iodide of potassium as high as 300 grains a day, with no effect. Excision of the testis advised on the ground that it was a sarcoma. This was done August 30. High excision of the cord was done. Careful examination clinically of the vas showed no invasion. When shown to the pathologist he immediately stated sarcoma, and was astounded at the result shown by microscopical section. It was then proven to be a tuberculous invasion of a general orchitis. The patient has been seen since, showing no secondary manifestations on the opposite side, nor has he at any time had any tuberculous manifestations.

Dr. F. Tilden Brown said that two months ago he had occasion to remove a testicle which, from the clinical history, led him to presume it to be of cancerous nature. After removing it and cutting into it he was still inclined to think the diagnosis correct. The pathologist reported, however, that it was tuberculous, and involved the testis and not the epididymis.

Dr. Eugene Fuller said he had a case some time ago that was apparently like the one reported by Dr. Erdmann. The testicle on section seemed to be studded with tuberculous foci and there were masses which looked like broken-down cheesy areas. The organ was quite large. Section of it was made and sent to the pathologist, but he reported it to be a sarcoma. Six months after this the patient again appeared with a sarcomatous liver. In this instance he said the patient had sarcoma when it was believed, on clinical inspection, to be tuberculosis.

Specimen of a Tuberculous Kidney.—Dr. F. Tilden Brown presented this specimen removed from the left side of a man aged thirty years. The diagnosis had been made by finding tubercle bacilli in the voluntary urine, and the localization of the disease then effected by ureteral catheterization. The patient was advised to take a period of rest, a change of air, etc., during the summer months. He returned from the woods for operation in October, having gained twelve pounds, and with less severe loin pain. Nephrectomy was simple and typical in all respects, except that the pedicle was exceedingly short, which made the operation unusually difficult. Although the preliminary exposure of the organ was a generous one, traction upon the areolar tissue and flaps with retractors was believed to be the reason for subsequent failure to get primary union. Fortunately the individual muscular and aponeurotic layers healed, but the skin wound fell apart throughout nearly its entire extent. In spite of an existing lack of ordinary reparative processes and the customary granulating surfaces in the superficial parts of the wound, the patient has in all other respects done very well. He voids a normal amount of urine and passes it only four times in twenty-four hours. In this patient's case, even before operation, the usual degree of frequency had not been a symptom. The intervals had averaged from three to three and a half hours. His first intimation of trouble consisted in noticing blood-tinged urine, together with left lumbar pain after a long swim in cold water. At the time of synchronous ureteral catheterization quite a number of small superficial hyperemic erosions of the bladder wall were noted through the cystoscope, mostly behind the left ureteral opening. They were such lesions as the speaker has elsewhere alluded to as not uncommonly associated with a renal tuberculosis, and regarding which he has satisfied himself as to the subsequent disappearance after removing the diseased kidney.

Dr. Eugene Fuller said that patients with pericystitis associated with contracted bladder were always left in a worse condition after drainage of the bladder than before. About ten days ago he saw such a case upon whom he refused to operate; the bladder was contracted and had been washed out for fifteen months, a procedure which had apparently aggravated the lesion; the whole interior of the bladder showed a granular mucous membrane, much thickened and shrunken. He believed that anybody who operated upon this patient would come to greatly regret having done so, for the bladder would shrink all the more as the result of drainage. The only thing to do in this case was to treat the patient therapeutically and hygienically.

Dr. Egbert Le Fevre said that in both private and hospital practice where there was pulmonary tuberculosis he had only observed a few cases in which there was a secondary involvement of the kidney or bladder. In the majority of the cases of genito-urinary tuberculosis there had been a secondary involvement of the testes. Whether his observations differed from those of genito-urinary surgeons he could not say. With regard to primary involvement of the genito-urinary tract with secondary involvement of the respiratory tract he had but two authentic cases; in two others with late pulmonary involvement they had the ordinary symptoms of bladder tuberculosis for some time previous. He examined the lungs at that time and made repeated examinations extending over 1½ years, even injecting tuberculin to see

if he could get any increase of physical signs that would warrant a diagnosis of pulmonary tuberculosis. Six months after the last examination one of the patients developed an apex lesion. In that case there was a pulmonary involvement three years after that of the bladder. He referred to certain experiments in which the tubercle bacilli had been injected into the bladders of animals and a secondary infection of the lungs had followed. These experiments were carried on to prove the theory as to the likelihood of tubercules being deposited in the apices of lungs by the blood-vessels, the bacilli being carried there from other parts, as the bladder. With regard to the treatment of genito-urinary tuberculosis, especially bladder, he had never had much permanent relief from surgical interference. In two cases in which there was primary involvement of the lungs the kidney symptoms entirely disappeared with the improvement of the pulmonary condition. He did not think the kidneys furnished a good soil for the growth of the tubercle bacilli and the occurrence of subsequent lesions. Only when there was a marked deterioration of the health was there any localization of the tubercle bacilli in the kidney which would be followed by a marked lesion. He asked Dr. Brown if, in the kidney case presented, there were any secondary deposits elsewhere in the body. He said that in the later stages of general miliary tuberculosis kidney lesions were rather common. Excluding such a general infection he said that one rarely saw such a marked implantation of tuberculosis, as was shown in the photograph of the kidney of the case, who was shown, except when it was done to extension from contiguous organs, or infection, blood going to one kidney by rupture of tuberculous material into it.

Dr. Eugene Fuller cautioned against too great an effort to make diagnoses through instrumental exploration in cases of suspected genito-urinary tuberculosis, lest a quiescent focus of tuberculosis be transformed into an active one. A patient may come to one feeling fairly comfortable; he may be simply urinating frequently, but without pain. If one should examine him with a sound, no matter how clean, or if he should search for a stone in the bladder and handle the instrument rather roughly, one may then stir up a great deal of discomfort, incontinence of urine, perhaps, and much pain, so that the patient would blame the surgeon for using the instrument. Before approaching such patients with instruments Dr. Fuller advised that we should try bacteriological aids first and go more into the history. If an instrument should be used the patient should be cautioned regarding the after-effects. In regard to the general question of operative surgery in these cases, he believed that we should lean toward conservatism. If there is not too much pyrexia he advocated the hygienic treatment; if there is much pyrexia and a suppurative focus, the latter should be gotten rid of in a surgical way and then therapeutic and hygienic measures should be adopted. He did not believe it was wise to operate upon a bladder when there was an active focus of tuberculosis elsewhere in the body; that is, if a kidney was involved he did not see any use in operating upon a bladder, even though it be involved, because this might stir up the tuberculosis in the kidney, and we might get other foci.

He said he was not as fond of the suprapubic operation for tuberculosis of the bladder as Dr. Johnson seemed to be. A few years ago Guyon gave it up and returned to perineal cystotomy. Once in a while one got good results from such drainage operations, but very frequently the results were deplorable. He said he was not as radical in the surgery of the genital tract as Dr. Blake, and he felt rather strongly against castration, as a rule, in those cases where the epididymis only was involved. In 90 per cent. of the cases where there was tuberculosis of the epididymis the testicle proper was not involved. He said he supposed he had removed epididymes and spared the testicles fifty times, and he had not left his patients with persisting sinuses. Recently a man appeared in his clinic from whom four years ago he removed the epididymis on one side. This patient when first seen had but one testicle, the other having been removed two years previously during an attack of tuberculous epididymitis. He then had an acute suppurative tuberculous process in connection with the remaining epididymis, and it was with difficulty the testicle was saved. That was four years ago. He is now a mentally satisfied man, with good sexual vigor. In cases of tuberculosis of one epididymis if the testicle is removed it was probable that within one or two years the other testicle would become involved. He believed that if the dissection was begun low down, peeling off a great deal by blunt dissection with the fingers, one could get the diseased portion away from the testicle without materially damaging its blood supply; but, if one began at the top and dissected downward, the blood supply would quite likely be disturbed. A man with a testicle, even though the epididymis has been removed, retains his masculine characteristics. He considered that a patient should not be deprived of his sexuality, except on the most urgent necessity.

Dr. Ellsworth Eliot, Jr. said it was often a very difficult matter to make a diagnosis of tuberculosis of the kidney during the early months from both subjective and objective symptoms. Two years ago in the medical wards of the Presbyterian Hospital a patient was admitted, who, for a number of weeks, had irregular fever and irregular abdominal pain, which pointed to the possibility of typhoid fever. This was finally excluded and he was transferred to the surgical division with a tentative diagnosis of appendicitis. During this time the pain did not remain in any one quadrant of the abdomen, although it did remain upon the side that subsequently was found to be that of the affected kidney. At the end of three or four months, during which time the urinary symptoms, notwithstanding the repeated examinations of the urine, failed to elicit the bacilli, the patient developed a tumor in the left flank. A diagnosis of some kidney difficulty was made, the kidney was removed, and found to be in a state of acute tuberculous necrosis, that organ being one mass of multilocular abscess cavities. He believed a radical procedure in cases of tuberculous kidney may be of benefit, but he realized that it was not always curative. He referred to a case of nephrectomy which was followed only by temporary relief in spite of the fact that the urine was apparently normal for weeks; yet the other kidney became affected, and, in the course of eight months after the nephrectomy, the patient died from tuberculosis of the opposite kidney associated with perinephritic abscesses. There were also extensive changes in the lungs which had not yielded physical signs eight months previously. He believed the limits of the operation should be extended, as for instance, in those cases in which tuberculosis was not necessarily limited to one kidney, or had invaded distant organs; in such cases in which tuberculosis invaded both kidneys he believed the kidney more affected should be removed when the daily amount of urea, and other solid material was not materially abnormal, and that the patient might recover and enjoy a respite from the disease with almost a complete subsidence of the tuberculous process in the remaining kidney. The end results in these cases were of interest. He referred to one case in which a left nephrectomy was done for a tuberculous kidney; at the same time there were tuberculous foci in the lungs in quiet condition, and a healed Pott's disease, tuberculosis and tuberculous cystitis of the pleura, and

yet the patient recovered from the nephrectomy and had had good health since. The operation was performed one year ago last August. He recommended nephrectomy when the tuberculous lesion appeared to be in one kidney only; here the end results were satisfactory. He said many cases, after such an operation, had remained well for from three, four, five, six or eight years.

With regard to tuberculosis of the testicle he said that where formerly he inclined toward the radical procedure of castration, within recent years he rather advocated the removal of the diseased tissue when limited to the epididymis. In many cases the disease seemed to be checked, the oldest case he had dating back 3½ years. A young doctor came to him with a tuberculous epididymis, and the patient objecting to castration, the tuberculous foci upon the diseased side were excised, requiring the removal of the epididymis. This patient made an excellent recovery and no recurrence has ever taken place, so far as any external examination could determine. Two years after the primary operation, however, he developed a tuberculosis of the opposite testicle, which yielded satisfactorily to the same therapeutic measure. The patient had been healthy ever since, and there has been no atrophy of the testicle on either side. In many cases he did not believe that atrophy need necessarily follow. If a part of the epididymis only be removed he believed that procreation, in certain cases, was possible.

Dr. A. A. Berg agreed that in the presence of secondary vesical tuberculosis, it was essential and absolutely necessary to attack the primary focus of disease. As a rule, secondary vesical tuberculosis healed, when the primary focus was removed, and the patients were placed amidst good hygienic surroundings. To him it was a peculiar fact that secondary vesical tuberculosis healed under the above conditions, whereas secondary ureteral tuberculosis manifested no such tendency. It is a good rule, therefore, to remove a tuberculous ureter at the time of the primary nephrectomy. He called attention to the pitiable state in which patients are often left after the tuberculosis of the bladder has healed. They have a contracted bladder holding from one-half to 1½ ounces; they must urinate every fifteen to twenty minutes, and are in consequence utterly unfitted for doing any work. Such a contracted bladder was especially likely to follow, if a suprapubic or perineal cystostomy had been previously performed. In the treatment of these miserable patients, who often look in the very best of health, we can do absolutely nothing, beside establishing a permanent bladder fistula. Attempts to distend the bladder usually fail to accomplish a lasting beneficial result. The patients are benefited for a time only; as soon as the local treatment is stopped, they relapse into their previous condition. These patients continue to be invalids. Regarding tuberculosis of the testicle he said that the experience of Dr. Blake was at variance with that of the best French and German observers. In a recent article in *Langenbeck's Archiv*, Vol. 70, Dr. W. Bogoljuboff showed experimentally that after partial and complete epididymectomy with implantation of the vas deferens into the remaining part of the epididymis or into the testicle, respectively, the spermatic channels of the rete testes communicated freely with the vas deferens. As to local recurrence after shelling out of tuberculosis areas in the epididymis or testes, he could recall two cases that had gone two years without such recurrence, the patients maintaining perfect health.

Dr. F. Tilden Brown said, in answer to Dr. Le Fevre, that so far as could be determined by a most careful examination, there was no other foci in the body. In the one particular case referred to the man had always considered himself healthy until after a swim in very cold water along the coast of Maine; he then noted a bloody tinge to the urine. With regard to suprapubic cystotomy for tuberculous lesions he said that the frequency with which permanent fistulæ followed these operations was due to the great carelessness in anticipating this possible complication, and in not making proper provision before the operation to treat the lesion actively when the suprapubic wound was made, treating the lesion with the sharp curette and cautery and other known therapeutic measures; and then to close the wound in layers providing only for little drainage in the prevesical space. He believed it to be a fallacy to leave the suprapubic wound to take care of itself, to heal or remain open, with the chance of becoming a source of great discomfort to the patient. He believed the surgeon should be prepared to know what he was going to encounter by doing a preliminary cystoscopic examination and then lay his plans for subsequent drainage; this may be had by continuous urethral drainage, or possibly perineal or vaginal. In cases of advanced contracted bladder every means should be taken to maintain a permanent suprapubic drainage until the end.

Dr. Joseph A. Blake said that he was glad to hear epididymectomy so unanimously recommended. When both sides were involved he endeavored to leave one testicle. Epididymectomy was not so good as castration for many cases in which the removal of the entire disease was important, and besides castration was a shorter operation. In regard to Dr. Eliot's case the chances of extension to the other side would have been much reduced if the vas deferens had been removed. Tuberculous disease should be treated in the same way as malignant disease, and if possible all the diseased structures should be removed; the vas deferens and seminal vesicle as well as the epididymis. In tuberculous glands of the neck, no one would think of removing one; the whole chain must be dissected out. Regarding the re-establishment of the continuity of the epididymis and vas deferens after epididymectomy, he could not believe, evidence to the contrary notwithstanding, that in a tube so slender that its twenty-two feet only occupied the bulk of the normal epididymis, that its lumen would not be occluded by the resulting scar tissue. For the same reason it was hard to believe that the vas could attach itself to the testicle. For these reasons he thought that the vas should be removed in all cases.

Dr. Ellsworth Eliot, Jr., said that it was a well-recognized fact that infection of the opposite testicle frequently followed even after castration. He took exception to the statement that if there was a tuberculous disease of one testicle the bacilli could (after ascending) go up the vas deferens, with or without evolvement of the seminal vesicles, bladder or prostate, travel in the opposite direction to the normal testes. If the other testicle was involved he said it was probably embolic. He referred to a recent article reviewing a series of experiments in which the writer had demonstrated that tubercle bacilli could not, in dogs, descend along the vas deferens to the testes, against the current of its secretion. He agreed with what was stated regarding excision of the epididymis, but excision of the vas deferens and the patient subsequently becoming the father of a child he doubted.

THE OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, held November 5, 1903.

The President, J. M. Fisher, M.D., in the Chair.

Observations on Gynecological Surgery in the German Clinics.—This was Dr. Charles P. Noble's paper, and consisted of critical remarks upon the operative work seen in the clinics of Professors von Rosthorn of Heidelberg, Olshausen and Mackenrodt of

Berlin, Leopold of Dresden, and Dr. Amann of Munich. Especial attention was devoted to the radical operation for cancer of the uterus as performed in Germany. Von Rosthorn has been performing the operation which he calls the "der erweiterte Freund" for three years and a half, with increasingly good results, so far as the primary mortality is concerned. One operation was witnessed in which the connective tissue and glands of the pelvis were removed from the bifurcation of the iliac vessels to the bottom of the pelvis, leaving the oburator nerves running free across the pelvis. The operation was done without hemorrhage, and completed, including the suturing of the abdomen by the stage method, in one hour and five minutes. The other German advocates of the radical operation are Wertheim, Mackenrodt and Amann. It is clear that more tissue can be removed by the radical operation than by the usual operation for cancer of the uterus. The mechanical and anatomical difficulties are such, however, that tissue must be left about the ureter and attached to the bladder and to the rectum. The operation is too recent for legitimate conclusions to be drawn, except as to the primary mortality. If this can be brought within bounds, the analogy of cancer operations in other portions of the body, especially the breast, will influence surgeons to do the radical operation in the pelvis, at least until the question as to the relative permanent results to be obtained by it and the less extensive operations is finally determined. Dr. Noble stated that, following Clark, some years ago he had done the radical operation for a time, but had abandoned it because of its increased primary mortality. The operation, as done by von Rosthorn, however, showed a marked improvement in the technic, which permitted the operation to be done in about an hour, instead of in two hours or two hours and a half. The chief advocate in Germany of vaginal hysterectomy for cancer is Olshausen, who advocates vaginal hysterectomy for cancer on the ground that the primary mortality is lower, and that if the disease is limited to the uterus, the operation is curative. He opposes the radical operation on the ground that if the disease has advanced beyond the uterus, the case is hopeless, no matter what operation is employed. The operation for retrodisplacement of the uterus as performed by von Rosthorn is quite similar to the original operation as introduced by Olshausen, the technic consisting in opening the abdomen in the middle line above the pubes, seizing first one and then the other round ligament near the cornua of the uterus, and suturing it to the abdominal wall on each side of the abdominal incision near the pubes. Dr. Noble reported a uretero-cystostomy performed by Prof. Mackenrodt after his method. The entire operation is extraperitoneal. The case reported was one of unusual difficulty because the ureteral fistule followed a radical operation for cancer by the Mackenrodt technic, part of which consists in stripping the peritoneum away from the abdominal and pelvic walls; hence, in performing the operation upon the ureter, when the peritoneum was detached from the abdominal and pelvic walls, it was not the separation of its normal connective tissue attachment, but the separation of adhesions resulting from the previous operation. Nevertheless, and in spite of these added difficulties, the operation was quite feasible and very satisfactorily performed. A report was made on various plastic operations performed by Prof. von Rosthorn and by Drs. Kehrer, assistant in the Heidelberg Frauenklinik, and Henckel, assistant in the Berlin University Frauenklinik. Plastic work in Germany is by no means so well developed or so well performed as is the abdominal surgery.

Dr. Noble stated that his various visits to the German clinics in the last six years showed a very marked improvement from every standpoint. This improvement is not only true of the mechanical part of the technic, but also of the asepsis. A very substantial improvement has also been remarked in the character of the hospitals and operating rooms. The newer hospitals in Germany, of which that of Leopold in Dresden may be taken as a type, are models of their kind.

Dr. J. G. Clark said that Dr. Noble's observations on German gynecological surgery are especially interesting, because of his mature judgment, and therefore his capabilities as a just critic. It was very interesting to him to know that the abdominal surgery as now practiced by German gynecologists is so much better than it was six years ago, when Dr. Noble made his last visit to these clinics. At that time Dr. Clark made the rounds of the German and Austrian clinics, and his impressions were the same as Dr. Noble's relative to the comparative superiority of American gynecology over that generally observed in these countries. In extenuation, however, of this apparent inferiority, he would say that at that time the furor for vaginal hysterectomy, which had sprung up in Paris and had spread over to Germany and Austria, was in full sway, and by far more pelvic surgery was being done by the vaginal than by the abdominal route. Since then there has been a general tendency, not only in Paris, but also in Germany, to return to the abdominal incision as the best means of reaching the surgical field in the pelvis. He believes, therefore, that the marked improvement which Dr. Noble noted is due to this fact. A short time since the advocates of the abdominal methods were apparently in the minority in Germany, whereas at no time has been this the case in the United States. There has, therefore, been a steady and continuous improvement in our country, whereas there was a period of three or four years in Germany in which there was from the abdominal surgeon's viewpoint retrogression, rather than progress in this line. As to plastic operations, his observations at that time were in accord with those expressed by Dr. Noble. Without question, this class of work is universally better performed in the United States than in Germany, and Dr. Clark believes the credit is due first to Emmet, and second, to the many students of Emmet, and Sims, who have practised and improved upon the methods of their teachers. In his entire rounds of the German clinics he does not recall having seen a single Emmet operation performed, the Tait and Hegar, or some modification of these operations, being universally in vogue. As the principles of these operations unquestionably do not possess the well-grounded anatomical basis of the Emmet operation, it is not especially remarkable that the results among our German, Austrian and French colleagues are not so good as those following the Emmet operation. Relative to hysterectomy for cancer as performed by Von Rosthorn, Mackenrodt, Wertheim, Krönig and others, it goes without question that they are all based upon the original operation as performed first by William Alexander Freund, and are, therefore, as von Rosthorn designated them, merely extended or widened (erweitert) Freund's operation. Relative to Wertheims operation, which is so much alluded to in gynecological literature at present, he regretted to see that the work of Werder, of Pittsburg, was constantly ignored. Werder unquestionably published the accounts of his operations first, and his principles are essentially the same as those described by Wertheim. So far as calling attention to the metastasis of the pelvic lymph glands is concerned, however, he would give the greatest credit to Wertheim, for he is the first operator

to systematically study serial sections of suspected glands. He has especially emphasized the importance of a serial study of the glands, and he has shown that the early stages of metastasis may only be demonstrated in isolated portions of even a small lymph gland; therefore, to take one section of such a lymph gland and upon finding it free of carcinomatous cells to pronounce it free of metastasis, is a fallacy. When Dr. Clark began the study of this subject in 1892 and 1893 he was convinced of the analogy between carcinoma of the breast and that of the uterus relative to early metastases. A study of the lymph glands, however, which were removed in these early operations, seemed to show that they were occasionally the seat of metastases, which appeared to destroy this analogy. It may be said, however, that Ries insisted, from the time he first described his more extensive operations for cancer of the uterus, that there is this early metastasis, and therefore, Wertheim's extensive study confirms his frequently repeated assertion. Notwithstanding the fact that he always performs the radical operation for cancer of the uterus, he attaches less and less significance to the extensive removal of the lymph glands as a curative measure, for he believes that if the glands are once infected a recurrence is almost inevitable, let the operation be as radical as possible. For the last three or four years he has considered the removal of these glands as of prognostic rather than of curative value. In summarizing his opinion, therefore, of the extended Freund operation, as performed by Wertheim, Mackenrodt, Krönig, and Von Rosthorn, he would say that it is the operation of preference, but only in the hands of skilled abdominal surgeons. Only by carrying out fully and accurately the details of these operations will be discovered definitely its range of usefulness.

Dr. R. C. Morris said that Dr. Noble is to be congratulated for taking the Society with him to the places he visited, and he thinks it would be well if more men who regularly go to Europe would systematically note what they saw and when they came back give the societies such a review of their visit. He was more especially interested in the radical operations for carcinoma, and it seems that Dr. Noble had that in his mind particularly. He was most interested to learn the ultimate results of the aggressive and radical work for cancer of the uterus. Personally, he is doing less and less; it is only in the earliest cases that he now does either vaginal or abdominal hysterectomy. He believes, however, that the work described by Dr. Noble's paper will enable us to finally settle this question of the permanent value of hysterectomy for cancer.

Dr. A. J. Downes said that in the past three years he had also noticed a vast difference in the work of surgeons all through Europe. Three years ago while in Europe it appeared to him that American surgeons were wonderfully superior in their technic to anything he saw there. He noticed this year that new operating rooms were springing up all over Europe. Leopold's particularly impressed him. Landau, of Berlin, also has a new outfit, which is equal to anything one would find anywhere. He also visited Mackenrodt with a view of seeing his cancer operation, but was disappointed; however, he saw a patient that he had performed it on and in this case there was a very large recto-vaginal fistule high up, which he repaired. One thing that struck him in Germany was that there were two camps, one class of men who still persist in doing vaginal work, and another class who prefer to do abdominal work. He asked one man, he thinks it was Mackenrodt, the cause of this, whether it was due to the fact that they had been doing this for a long time and before it was possible to do such aseptic surgery as is done now. He remembered asking Kümmel in Hamburg the same question. He agreed that the men who early started to do vaginal work persist in it. He noticed one of the men who does a vast amount of vaginal surgery, when he did a fairly difficult operation for large fibroid through the abdominal incision, was not equal to control of hemorrhage anything like a man who usually does abdominal surgery.

Dr. Charles P. Noble, in closing, said that he was especially interested this year in trying to see what is being done with the radical operation for cancer of the uterus. When Dr. Clark first began doing this operation in this country he did it for a while. It took him two hours and sometimes longer. The primary mortality in his hands was not encouraging, so he gave it up. He was interested in the matter, because he wanted to see how other men managed it. If every case could be dealt with as beautifully as von Rosthorn's he believed we would all do it, because one can remove more tissue than by the ordinary methods of operation.

Paralysis of the Abdominal Sympathetic and Fecal Impaction Following Labor; also a Case in which Death from Hemorrhage Followed Premature Labor.—These were the themes of Dr. Edward P. Davis' paper. Paralysis of the abdominal sympathetic may be observed after delivery in cases where the fetus is unusually large, in polyhydramnios and in exhausted women; it may be associated with post-partum hemorrhage and the depressing effects of both lead to a fatal issue. The patient reported was a multipara pregnant for the second time, in whom paralysis of the abdominal sympathetic occurred after the delivery of a normal fetus when hemorrhage was absent and where the mother was apparently not exhausted. The great abdominal distention, the patient's very rapid and feeble pulse, the tension in the intestine, the temperature, the continuance of normal lochia and the final recovery of the patient identify the condition as one of vasomotor paralysis, accompanying toxemia of intestinal origin.

Case II.—The woman was twenty-three years of age and in her third pregnancy. Her previous labors had been spontaneous, but were long and severe. She was markedly anemic. For six weeks she had daily bleeding. She was seven months pregnant upon admission to the Jefferson Maternity and remained in bed until the termination of labor, ten weeks later. There was no evidence of placenta previa. Hemorrhage ceased when she was put to bed. When labor occurred there was delay through inertia, complete dilatation was secured artificially and a living child delivered by forceps. The mother made a good recovery and left the hospital with her child in fairly good condition. About eighteen months afterward this woman was again admitted to the Maternity, five months pregnant, and she had had severe hemorrhages. The patient was soon delivered, and did well for a week when hemorrhage recurred. The uterine cavity was carefully explored, found empty, and was packed with iodoform gauze. The hemorrhage ceased, to recur a week later, and controlled in the same way. Two weeks later another severe hemorrhage occurred which was also controlled by gauze packing. The patient died two weeks subsequently of exhaustion following a return of the hemorrhage. In the absence of a history of hemophilia and placenta previa, it is difficult to find an adequate explanation for the hemorrhage. Scyntioma malignum presents itself as a possible and even probable explanation, and a more complete autopsy might have given evidence of its presence. There was no fibroid growth present in the uterus, nor was there any other lesion of the pelvic organ. No measure, except compression

by gauze, seemed to influence the bleeding. At no time did the patient's condition justify hysterectomy.

Dr. R. C. Norris said that both the cases that Dr. Davis reported are of great interest, and as he was reporting them Dr. Norris cast about in his mind to recall analogous cases. In the first place he should like to speak of the question of fecal impaction and fecal toxemia following labor. It has been his fortune to be worried on several occasions over his patients in the Preston Retreat by finding an elevation of temperature, which, however, would rapidly disappear after the free administration of purgatives and high enemas, enormous quantities of fecal matter being discharged. In hospital practice it is by no means uncommon, but on the contrary, quite common, for pregnant women to have stored up in them large accumulations of fecal matter with greater or less degree of toxemia. He recalls particularly a case of enormous abdominal distention, and some of the gentlemen here may recall this also. He was requested by telephone message to admit to the Preston Retreat a case of extra-uterine pregnancy. The doctor in attendance the preceding day had attended the woman in labor at full term, and had delivered her of a child through the natural passages, and then discovered an extra-uterine gestation. While in transit to the hospital all preparations were there made for an abdominal section, but upon arrival she was so ill (enormously distended, and with a pulse about 140, temperature 104° F.), and not being able to palpate her abdomen and locate the extra-uterine mass, it seemed wise to attempt to purge her and to wait until the following morning. From a necessarily superficial examination of her abdomen, on account of the enormous distention, he could find nothing abnormal indicating an extra-uterine fetus. Effort failed that night to get any movement. There was fecal vomiting. Next morning all the preparations for abdominal section were made, and several physicians were present to witness this extraordinary case. After administration of an anesthetic it was possible to palpate her abdomen, and it was learned definitely that there was no extra-uterine fetus; that there was a fecal mass apparently plugging the bowel, and under the anesthetic this enormous accumulation of flatus diminished, and with free purgation later disappeared; and, in the course of a week the patient was convalescent and went home. Of course, no operation was done. Enormous quantities of fecal matter were obtained by high enemas given to the patient in the Trendelenburg posture. He found in that case, as he had in others of distention following labor, that the use of a many-tailed bandage is a great comfort to the patient, and of very great importance to assist in the elimination of the flatus. The high enema of milk of asafetida with a many-tailed bandage seemed to do more good than any other medication. This was the most extreme case he had ever seen. He remembers seeing with Dr. Boyd in the wards of the Lying-in Charity, a case of enormous distention—one could see the coils of intestine through the over-distended abdominal wall. In one of his cases he found it necessary to open the abdomen and puncture the intestines to let out the gas. He believes that patient's life was saved by this measure. This was the only occasion on which it appeared desirable or necessary to resort to so heroic treatment. The case he has referred to to-night will be reported in detail in the report of his work at Preston Retreat. He wished to impress the fact that the fecal accumulation, with distention and temporary fever, particularly in hospital cases, is really a very common condition, so much so that his head nurse, who has seen over 3,000 confinement cases in the Retreat, rigidly enforces his rule that all waiting patients are to be daily purged freely with salts and licorice powder to prevent fecal accumulation and fecal intoxication. He has also a case in mind, not wholly analogous to Dr. Davis' case of hemorrhage. The patient had the tendency to bleed during pregnancy and when she came under his care was exceedingly pale from anemia. She had profuse hemorrhage forty-eight hours after her labor, and in spite of a gauze plug, she kept oozing a clear serum. The nurse thought she was passing urine involuntarily, so little colored blood did she appear to have in her body. Dr. Allen found she had only 15 per cent. of hemoglobin. This case also will be reported in detail in the forthcoming report of work in the Preston Retreat. All means of stimulation were tried, and the more salt solution given, the more she simply wet the bed apparently. There appeared to be no ability on the part of her blood to coagulate. The patient finally died of enemia. He concluded that there was a failure of clotting in the uterine sinuses through the character of the blood itself. If he should ever meet a similar case he should use adrenalin. It seems to be one of the newer drugs that may prove useful in that kind of bleeding following labor. Dr. Davis' case certainly suggests malignant disease. In Dr. Norris' experience the cases of hemorrhage are very rare, the cases of fecal impaction and of abdominal distention are not uncommon. The cases of enormous abdominal distention with apparent nerve paralysis are certainly very rare.

Dr. Charles P. Noble said he had seen a number of cases somewhat similar to Dr. Davis' case of fecal impaction. It is always a question in these cases whether the bowel paralysis is primary or influenced by fecal impaction. He thinks fecal impaction is the primary trouble. It so happens that he also saw the case alluded to by Dr. Norris in the Lying-in Charity. He remembers the distended bowels which one could feel through the abdominal wall. The woman had the ordinary symptoms of obstruction. His recollection is that an abdominal section was done and nothing at all found. In abdominal work he has frequently had these cases of fecal impaction with toxemia, and he thinks that not only is it very important in treating these cases to irrigate the colon, but it is also very important to wash out the stomach. A great many of these patients die from absorption from the stomach. He once opened the abdomen, supposing that the patient had an obstruction with distended bowels. When he opened the abdomen he discovered the entire distention was due to a very full stomach. While the woman was on the table a stomach tube was introduced, and the abdominal distention disappeared into the bucket. Since that very striking case he has always dealt with these cases by washing out the stomach as well as the bowel. By the stomach tube we can far more surely introduce cathartics than in the ordinary way. As a rule it is useless to give cathartics; they simply cause vomiting and are useless. By first washing out the stomach, and using salts or some other cathartic we are usually able to get good results.

Dr. Stricker Coles said in regard to the second case Dr. Davis reports, that of hemorrhage, when he first saw this patient she was ten or twelve weeks pregnant. He had never seen as much blood lost and the patient still go on with pregnancy. He told her she had lost the embryo. On making examination the uterus seemed much smaller than it had been when he had examined her two weeks before. She was in bed from this hemorrhage for some little time. He gave her a rectal injection of a large amount of salt solution. She was almost pulseless at the wrist when he saw her. He had been late in getting to her. She recovered from that and came down to see him about three weeks later,

making about the sixteenth week of gestation. He found that she was still pregnant, and she went on with the pregnancy, having slight hemorrhages off and on. When she came into the Maternity she was in a fair condition, and her delivery was accomplished with ease. There was no hemorrhage after it and she was making an apparent perfect recovery when the first hemorrhage occurred about ten or twelve days afterward, and this hemorrhage came on without apparent cause. The woman was seemingly nearly well enough to get out of bed, and this hemorrhage was so easily controlled by packing that she revived speedily. The hemorrhage was profuse while it was short, and she would probably have bled to death had it not been promptly controlled. We packed the uterus on these occasions and could find nothing apparently out of the way.

Remarks on Cæsarean Section.—This was the subject of Dr. G. M. Boyd, who said that during the past seven years in treating dystochia due to pelvic deformity, he had found it necessary to resort to Cæsarean section in eleven cases. Eight of these cases were operated upon prior to 1903, and have already been reported. Of the three patients operated upon this year, one had a generally contracted pelvis and a true conjugate of 8 cm.; another a generally contracted rachitic pelvis, with a true conjugate of 7.5 cm.; and the other a rachitic pelvis with a true conjugate of 7.5 cm. A living baby was secured in each case, and the mother made a good recovery. Celiohysterotomy was the operation of choice in each case. Of the entire series of eleven cases, with the exception of one dead child, the list is without a mortality. One patient had lost one child; two patients had lost two children; one patient had lost six children. There were three repeated Cæsarean sections; in four patients the elective operation was performed; in seven there was the test of labor; in all the elective cases there was a history of one or more labors, ending disastrously to the child.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, held December 1, 1903.

The President, Pearce Bailey, M.D., in the Chair.

Case of Brain Tumor with Autopsy.—Dr. William M. Leszynsky reported this case. The patient was a girl aged nineteen years, a stenographer and typewriter by occupation. She was admitted to the Eye and Ear Hospital on January 12, 1903, and was seen in consultation with Dr. H. Jarecky. She was totally blind as a result of intense papillitis. The eyeballs were slightly prominent and rigid. She had never indulged in alcoholics, but had used tea excessively. Nine months ago she had begun to suffer from unusually severe occipital headaches, generally at night while asleep. The more severe attacks were accompanied by vomiting. There had also been severe attacks of vertigo. Two months previously she suddenly became blind in the right eye, and one month later the left eye became similarly affected. She remained in the hospital about two months, during which time she complained of frequent and severe headache in the right temporal and parietal regions, associated with tonic left facial spasm. Involuntary urination occurred from time to time. There was a slight paresis of the left facial distribution. The left knee-jerk was more pronounced than the right, but ankle clonus was absent. The urine was negative. The pulse was about 78. She received a thorough course of iodide of potassium and mercurial inunction without improvement. His diagnosis was cerebral tumor involving the right hemisphere. She was admitted to his service at Lebanon Hospital on March 7, but would not consent to an exploratory operation. She could not recognize by touch any familiar object with the left hand. The convulsive attacks gradually increased in frequency, there being later clonic movements of the face, and nystagmus with retraction of the head. On May 18 there were several attacks of sudden vertigo associated with tonic and clonic spasm of the left side of the face and left arm and leg. Toward the end of May, in addition to a pronounced facial paralysis, the orbicularis palpebrarum became decidedly paretic a few weeks later. The Babinski reflex was exquisitely demonstrable on both sides. During her stay in the hospital the pulse varied between 98 and 100, the respirations were 24 and the temperature 98° to 99° F. On May 30 she was admitted to the Presbyterian Hospital to the service of Dr. McCosh for operation. On June 6, while conversing with Dr. Leszynsky, she suddenly became unconscious, and the limbs were rigidly extended. Both eyes were closed, the face was pale, and the pulse was regular. There were no clonic movements. After about three minutes there was complete muscular relaxation, and rapid and almost abrupt return to consciousness. On June 9, Dr. Starr concurred in the diagnosis and thought there might be multiple lesions. Two radiographs were made, one anteroposteriorly, and the other laterally. The operation was done on June 11, 1903, under chloroform, a flap being raised over the fissure of Rolando. The intracranial pressure was found to be markedly increased. At the depth of an inch and a half, in the direction of the right lateral ventricle, cerebrospinal fluid was reached. No tumor formation was discovered. A silkworm-gut drain was inserted, and after operation between one and two pints of this fluid drained away each day. Following the operation there was, for a short time, a complete left hemiplegia with rigidity. She died on July 8 from lobar pneumonia, four weeks after the operation and seventeen months after the symptoms of brain disease. The autopsy was made fifteen hours after death by Dr. George A. Tuttle. The examination was limited to the brain and its contents. The brain tissue in the region of the operation was quite soft. A soft red mass was found in the right ventricle, about the size of an egg, which apparently sprang from the inner wall of the ventricle. The tumor was thought to be a glioma. There were two organized blood clots in the ventricle. Macroscopically, all the other portions of the brain and meninges appeared to be normal.

Dr. J. F. Terriberry said that he had seen this case at the Manhattan Eye and Ear Hospital. The astereognosis was one of the most prominent symptoms at that time. The young woman had spasmodic contractions of the face muscles, first on one side and then on the other. The importance of the astereognosis as a localizing symptom had been forcibly impressed upon him by this case. If these symptoms coming from the basic area of the brain had occurred earlier, they might have led to an erroneous diagnosis.

Dr. George W. Jacoby said that the most interesting part of the report to him was the demonstration of the X-ray plates. In the skiagraphy of tumors of the brain we possessed a very valuable adjunct, but we should insist upon more precision in the description of these examinations. Over a year ago he had exhibited to this Society two skiagraphs of a case of tumor of the brain, taken during life. The patient was subsequently operated upon, and the tumor removed, and the patient lived five months longer. This case proved the feasibility of obtaining skiagraphs of practical value in these cases of tumor of the brain. Oppenheimer's experiments in this direction were very interesting. He had experimented with a hardened tumor in the brain and with a hardened tumor within the skull, and had succeeded admirably, but had failed on attempting to photograph

brain tumors during life. Dr. Jacoby said that he had repeated these experiments, and had discovered that when soft or fresh tumors were used the result was not successful. Since that time he had made many clinical examinations on supposed brain tumors without obtaining a single positive result until the one presented by him a year ago. This experience showed that one should work with a known tube and with a known exposure to determine what would give a complete transillumination of the skull. Having done this, the minimum exposure should be used, say 7½ or 8 minutes, and then each successive exposure should be made a little longer. In his own successful case exposures of 10½ and 11½ minutes, respectively, were successful, whereas longer and shorter exposures led to failure. It had been thought by some observers that the result would only be successful with a thin skull and a hard tumor, but in his own case the bones of the skull were thick and the tumor friable.

Dr. Leszynsky said that within the last two months he had examined two patients who undoubtedly had brain tumors, which could not at the time be accurately localized. In each case there was astereognosis present on one side, yet when seen again the astereognosis had disappeared. These patients were examined a great many times, and it had been noted that the astercognosis was very variable, being present at one time and absent, perhaps, half an hour later.

Is Epilepsy a Functional Disease?—Dr. M. Allen Starr was the author of this paper. He said that he had come to the conclusion that epilepsy was an organic disease, and this opinion was based upon a personal study of two thousand cases of epilepsy of which he had satisfactory records. The recognition of Jacksonian epilepsy of several different types was now universal. This form was admitted to be a symptom of organic disease, though the nature of the latter might vary considerably. The character of the attack was uniform because the disease produced a uniform kind of irritation. In 38 per cent. of his cases of ordinary epilepsy the attack was preceded by an aura, which was identical in many cases with the sensation starting a Jacksonian attack; the only difference between a Jacksonian attack of the motor type and the idiopathic form was in the extent of the spasm. The Jacksonian attack might run into a general motor spasm, showing that there was no essential difference between the two. The same might be said of the sensory attack. In many cases the fit began with a cry, a discharge from the motor speech center. If the Jacksonian attack became severe and widespread, consciousness was apt to be lost. The close resemblance in 23 per cent. of his cases between Jacksonian and ordinary epilepsy seemed to him to offer an argument that, in these cases at least, the ordinary type of epilepsy was due to organic lesions. Another argument in support of his proposition was found in a study of cases of maldevelopment of the brain. Of 400 of such cases, elsewhere analyzed, 156, or 39 per cent., were subjects of epilepsy. It was not uncommon to suppose a child to be suffering from epilepsy only, and yet careful inquiry showed a previous apoplexy. Among his two thousand cases of epilepsy, 192 showed positive signs of maldevelopment of the brain. Of his cases of epilepsy, 68 per cent. developed before twenty years of age; in other words, during the period of brain development. The speaker maintained that many cases of idiopathic epilepsy were actually cases of maldevelopment of the brain, and that the epilepsy was the manifestation of this organic disease. The incurability of epilepsy afforded another argument for the organic nature of this disease. There was no question that proper care and treatment could reduce the frequency and sometimes mitigate the severity of the attacks. He had come to the conclusion that the surgical treatment of epilepsy by exposing the brain and removing irritating foci, offered as little hope for cure as did medical treatment. He had records of about fifty cases of Jacksonian epilepsy treated by trephining, and he had yet to see a case in which such operative treatment had been followed by a permanently satisfactory result. Another argument for the organic basis of epilepsy might be found in the alleged causes of the disease. The first of these was heredity; the second in frequency was trauma of the head. That trauma of the head was a more potent cause than trauma elsewhere was well shown by the statistics of the Franco-Prussian war. These showed that out of 8,895 wounded in the head, 46 became epileptic, whereas out of 77,463 persons wounded elsewhere only 17 became epileptic. The epilepsies of advanced life could almost invariably be traced to endarteritis and atheroma. Fright was undoubtedly a cause of this disease, as 119 of his patients had the first fit after a severe fright. One great stumbling block to the adoption of the theory of the organic origin of epilepsy was the multiplicity of causes enumerated by pathologists. The epileptic attack was the symptom, not a disease; the disease was a disorder of control. It seemed to him far more reasonable to admit that epilepsy was an organic disease of the brain characterized by a lack of control of the mechanisms over motor energy. If we adopted this rule, we would more readily admit that it was incurable, and would be more willing to aid in the establishment of colonies for epileptics.

Dr. C. L. Dana said that he was surprised that the author apparently assumed that we did not believe that epilepsy was an organic disease. At least ten years ago, the speaker said, he had spoken of epilepsy as a progressive degenerative disease of the brain, but as we did not yet know always what was this degeneration, or where it was, and could not give a morphological description of the diseased cells, it was probably wise to still describe epilepsy among diseases without definite organic basis. He also doubted if the term disease was the proper one to use in connection with epilepsy. There was certainly an underlying organic degeneration, but it seemed to him that in many cases it was rather a morbid condition than a disease process—rather a teratological defect than an actual disease. So far as we knew now it was probable that the most important factor underlying epilepsy was the tendency of large groups of nerve cells to undergo a rather progressive degenerative process. With regard to the argument about Jacksonian epilepsy, he would say that the author's statements were not strictly correct. Some forms of Jacksonian epilepsy were as much without known organic basis as ordinary idiopathic epilepsy. He had had a case of Jacksonian epilepsy with classical convulsions confined to one arm and one side of the face, lasting for years, and after death a modern autopsy gave absolutely negative results. With regard to the incurability of epilepsy he would say that the stand taken by Starr seemed to him not only incorrect, but disheartening and unfortunate. He absolutely knew of cases in which epilepsy had been cured. He knew personally of a young man who, at the age of seventeen, had nocturnal epilepsy for one or two years, the attacks coming as often as two or three times a month. He had seen the attacks himself, and they were perfectly characteristic. Under the bromide treatment this man recovered, and was now forty-five years of age, and had never had an attack since. There were now none of the interconvulsive symptoms of epilepsy, and this disease should be looked upon as cured just as much as a pneumonia might be considered cured. He had another patient who had been well for twenty years, and another for fifteen years. The very theory of the disease, assuming

it to be organic, would make a cure possible. We knew perfectly well that there were certain degenerative processes that we could arrest; for example, tabes and degenerative processes affecting the kidneys or liver, for degenerative processes were not always progressive.

Dr. L. Pierce Clark said that Dr. Dana's statement about the curability of epilepsy had interested him, because, in an experience of ten years with epilepsy, he had records of at least two or three dozen who had remained free from epileptic attacks for periods varying from eight to twenty years. It was true that they might run eighteen or twenty years and recur again, but in such cases he would look upon them as practically cured, although the original condition might still persist. He agreed with Dr. Starr that idiopathic disease had an organic basis. He did not believe that the mere existence of an organic disease of the brain was sufficient to account even for the epilepsies of the Jacksonian type. He believed that perversions of nutrition or toxic agents were potent factors.

Dr. William Hirsch asked Dr. Starr for a definition of what he called organic or functional. From a strictly biological point of view, he thought, we could not make such a distinction between organic and functional. That a disease was organic did not by any means justify us in calling it incurable. When one made a diagnosis of paranoia, one knew that it was an incurable disease, and yet it was classified all over the world as a functional disease, because no one had as yet detected any organic changes in the central nervous system. The fact that Jacksonian epilepsy was frequently due to organic changes, which we recognized as such, did not prove that general epilepsy must have a change analogous to that of Jacksonian epilepsy. As Dr. Dana had pointed out, there were cases presenting quite characteristic attacks of Jacksonian epilepsy. He had in mind cases of general paresis, and particularly one case, in which death had been preceded by a very large number of these attacks, yet a careful autopsy on this patient was absolutely negative. On the other hand, there were cases of organic disease, tumors of the brain and arteriosclerosis in which epileptiform attacks never took place. We were all familiar with eclamptic attacks, attacks due to poisoning, and dependent upon transitory changes in the brain. It was manifest that all cases of epilepsy could not be said to have an organic basis.

Dr. William H. Thomson said that the function of a lamp was to give light, and for that purpose its structure might be a glass globe, a wick and a reservoir of oil. If any portion of that structure were damaged it might interfere with its light-giving function, but this same function could be entirely abolished without in any way interfering with its mechanism, *i.e.*, by supplying it with water or poor oil. Similarly, he conceived functional nervous diseases as truly derangements of the source of nerve function, independent altogether of the structure of the brain, *i.e.*, the blood. Functional disease might be so serious as to terminate life, and yet no nerve cell or fiber could be demonstrated to be diseased, the disorder perhaps having been entirely due to a toxin in the blood. He could not believe that a disease characterized so strikingly clinically by intermittency as was epilepsy could consist essentially in a structural lesion, nutritive or otherwise. He fully agreed with Dr. Starr that epilepsy was not curable by the surgeon, and, indeed, that a surgical operation upon the brain was apt to be followed by epilepsy. A polypus of the nose sometimes gave rise to an intermittent nervous trouble, asthma. He had had a number of cases in which the removal of a peripheral source of irritation had been followed by a permanent disappearance of epilepsy. With regard to the true pathology of epilepsy, we were often misled in regarding epilepsy as due to a discharge in the cerebral cortex. This notion he could not reconcile with the fact that every efferent impulse was always secondary to an impulse from the afferent side. His definition of epilepsy was "a *sudden* derangement of the normal inhibition of cortical centers upon one another, dependent, in the first instance, upon an abnormal afferent impression." The majority of cases of epilepsy he believed to be the result of toxemia. That epilepsy, with such widely varying manifestations, should be dependent upon one organic disease of the brain, he could not believe.

Dr. S. F. Hallock thought if we carefully investigated the psychical side in the early history of many cases of epilepsy we would obtain a strong argument for the organic origin of the disease.

Dr. Joseph Collins said that he personally felt no urgency in putting epilepsy into the camp of organic diseases, neither did he think Dr. Starr had presented any reasons for such urgency. That we might find epilepsy to be an organic disease he hoped, and he also hoped that if such discovery were made we would find the means of coping with this disease; yet Dr. Starr seemed to take a hopelessly antagonistic view on this point. Personally, he had never been taught to look upon Jacksonian epilepsy as an organic disease, the point upon which Dr. Starr seemed to found his main argument. He supposed that about 25 per cent. of the cases of idiopathic epilepsy presented Jacksonian attacks, but this phenomenon he looked upon as only an indication that the irritation proceeded from a certain portion of the brain. He understood this was Hughlings Jackson's view. He knew of no organic disease which came on in the first decennium of life, and continued practically for the full natural term of life; in other words, a disease that did not cut life short. He did not know of any cases of epilepsy which had been studied in the intervals of the attack, except where the observations had been interfered with by medicinal treatment to such an extent as to render these observations of no value. It had been stated this evening by several persons that changes in the brain in epilepsy had been found with a certain degree of constancy by well-recognized neuropathologists. He would say that these changes were not to be compared in any way with those which occurred in the cell bodies of the neurons in a case of poisoning by bromide of potassium, administered accidentally to a patient in Toronto a year or two ago. He thought Dr. Starr must be persuaded to modify his statement regarding the incurability of epilepsy before the publication of his paper, because it would otherwise give rise to an almost immeasurable amount of despair. He did not think there was any real justification for such pessimism. Personally, he knew that cases of epilepsy did get well, or at least practically so, and he believed we were already able to cope with epilepsy with fair success.

Dr. Thomas Prout said that he had studied a good deal of pathological material sent him from the Craig Colony by Dr. L. Pierce Clark. The cases dying in status epilepticus presented a uniform lesion of the cortex. In ordinary idiopathic epilepsies he found the same lesion in the cells of the cerebral cortex, but in lesser degree, and he looked upon these changes as characteristic of epilepsy. A case reported by Wright had attracted considerable attention, but this observer's methods were exceedingly faulty. The autopsy in his reported case was made fourteen hours after death, and the body temperature was 108° F.

Dr. Adolf Meyer asked Dr. Starr what attitude he took concerning the fact that he founded his conclusions upon the occurrence of focal symptoms in such a large number of cases of epilepsy. What would he say with regard to the fact that the removal of such lesions failed

to cure the epilepsy. The word organic as commonly used implied something far more serious than the disease as described by Dr. Starr. The persistence of the epilepsy after the removal of the organic lesion would seem to indicate that there was a general disorder present.

Dr. W. M. Leszynsky said that after a number of years of clinical experience he certainly disagreed with Dr. Starr in his pessimistic views as to the curability of epilepsy. It could hardly be doubted that a certan proportion of the cases of idiopathic epilepsy were cured. Reference was made to two cases in which the patients had promptly improved, and had been practically free from epileptic attacks for several years after the bromides had been discontinued, and proper attention had been given to the general health.

Dr. Max G. Schlapp said that it should not be forgotton that epileptiform convulsions could he produced by many different things; hence, to take a symptom or a group of symptoms and dignify them with the title "organic disease," seemed to him to be going too far. We knew that in children convulsions could be brought on easily by slight irritation of the peripheral nervous system, and to say that these convulsions were produced by an organic lesion in the central nervous system was not justified by the transitory nature of these symptoms. The difference between a Jacksonian epilepsy and an ordinary epilepsy was perhaps to be found in the position of the lesion. If the irritation were beyond the motor center it was possible that the irritation would spread throughout the cortex, giving rise to unconsciousness and various central disturbances. The lesions described by Dr. Prout as occurring in epilepsy were found in other conditions. The principal lesions found, according to the Nessl method, were chromatolysis, and might be present in connection with various forms of poisoning.

Dr. Edward D. Fisher said that he had long believed epilepsy was an organic disease. The fact that we could produce convulsions similar to what we understood as epilepsy, did not necessarily mean that they were really epileptic. The characteristic of epilepsy was its persistence; it was the general mental state as well as the convulsion which constituted epilepsy. We should sharply distinguish between idiopathic epilepsy and epilepsy due to any other non-irritating cause. He did not think Dr. Starr meant to give any definite pathology for epilepsy, but merely to state that it was an organic disease. He could not agree entirely with him, however, regarding the incurability of epilepsy, although he would admit that it probably was the most nearly incurable disease known. He could not conceive of a disease which went on year after year with exactly the same symptoms as at the beginning, without there being back of it an organic lesion.

Dr. Starr closed the discussion. He said he was exceedingly obliged to the society for its full and free discussion of this important topic. He was willing that his statements about the incurability of epilepsy should not be published; nevertheless, he believed, with Dr. Fisher, that epilepsy was one of the most incurable diseases we were called upon to treat. It was true that the various speakers had spoken of one or two recoveries, yet those present must have seen hundreds of cases of epilepsy. He thought this substantiated fully the position he had taken with regard to the general incurability of epilepsy. He had had no idea of establishing a pathology for epilepsy. He certainly regarded, and believed most neurologists regarded, the Jacksonian cases as organic. The same sources of irritation which gave rise to epileptic attacks were present constantly in other individuals, and hence, there was something else in epileptics. He believed in epileptic persons there was, in addition to the toxemia, some underlying defect, as Dr. Dana had said. It was certainly very important to study epileptics in the intervals of the attacks, and when not under medicinal treatment; he had done this frequently, and believed it was being constantly done by others.

CORRESPONDENCE.

A MEETING IN BALTIMORE TO DISCUSS THE TUBERCULOSIS CONGRESS SITUATION.

To the Editor of the MEDICAL NEWS:

On January 28, 1904, at 8.15 P.M., there will be held in Baltimore, at McCoy Hall of the Johns Hopkins University, under the auspices of the Maryland Tuberculosis Commission, an informal meeting of American physicians and hygienists interested in the tuberculosis problem of this country. The object of the meeting will be to form a national committee to represent the American medical profession at the International Congress on Tuberculosis to be held in Paris in 1905. There will also be a free discussion of the announced Congress on Tuberculosis in St. Louis under the leadership of Mr. Clark Bell, and the other tuberculosis congress to be held in Washington in 1905 under the leadership of Dr. Daniel Lewis, or as it is now called "The American Anti-Tuberculosis League." It is to be hoped that the deliberations at this meeting will result in an understanding between all parties concerned, and that all individualism and partisanship will be supplanted by true love to humanity, by genuine scientific and practical methods, and by the highest professional motives. If it is the unanimous opinion of the medical profession that there should be an American Congress on Tuberculosis previous to the one which is to meet in Paris next year, it should be thoroughly representative and an honor to the American medical profession.

Professor Wm. H. Welch of Johns Hopkins has kindly consented to preside. All communications relating to this meeting should be addressed to the Secretary *pro tem*, Dr. H. Barton Jacobs, 11 Mount Vernon Place, Baltimore, Md.

[Those of the readers of the MEDICAL NEWS who are not yet familiar with the present tuberculosis congress situation in America we beg leave to refer to an open letter by Dr. S. A. Knopf of this city, entitled "American and International Tuberculosis Congresses and Tuberculosis Exhibits for the years 1904 and 1905," which appeared in the NEWS of December 5, 1903.—ED.]

BOOK REVIEWS.

A TEXT-BOOK OF OPERATIVE SURGERY. Covering the Surgical Anatomy and Operative Technic Involved in the Operations of General Surgery. Written for Students and Practitioners. By WARREN STONE BICKHAM, Phar. M., M.D., Assistant Instructor in Operative Surgery, College of Physicians and Surgeons, New York; Late Visiting Surgeon to Charity Hospital, New Orleans, etc. Octavo, 984 pages, with 559 illustrations, entirely original. W. B. Saunders & Co., New York, Philadelphia and London.

THIS is undoubtedly one of the important books of the year and both its author and publisher are to be congratulated on its appearance. A large meed of praise is due, however, to Miss Eleanora Fry, who drew all of the extremely numerous illustrations. The value of books of this sort depends largely on the character of the illustrations, for one glance at a skilfully pre-

pared drawing will do more toward refreshing the memory or making clear an unfamiliar form of technic, as an intestinal suture, for example, than the perusal of pages of letter press. In this instance the artist's work has been done with unusual care and the result has been signally successful.

Even the very few borrowed pictures have been entirely redrawn and brought into harmony with the others, so that the entire series is uniform and gives an impression of homogeneity very different from the usual indiscriminate hodge-podge of cuts, where all epochs of surgical development and degrees of draughtsmanship are huddled side by side. The text, however, is fully worthy of all the artistic embellishment possible and is arranged with a system, an economy of verbiage and a clearness of expression that leaves nothing to be desired. It is fully modern in all its phases and the author's experience in Tulane University has enabled him to describe numerous procedures not commonly practiced in this part of the country. Among these are several of the ingenious devices of Matas, a surgeon whose work is not as well known in the North as it should be. Pfannenstiel's suprapubic incision is described, for the first time, we believe, in an American text-book, but we think that Crile's method of clamping the carotids during neck operations might be included in the section on "Temporary Ligation of Arteries" and we miss an account of the Connell-Turk modification of the Maunsell suture of the intestine. The mechanical make-up of the volume is in keeping with the text and adds its part to the production of what is without doubt the finest single volume operative surgery we at present possess.

A Text-book of the Diseases of Women. By Thomas A. Ashby, M.D., Professor of Diseases of Women in the University of Maryland; Consulting Gynecologist to the Mount Hope Asylum, etc. With 233 illustrations. Williams & Wilkins Company, Baltimore.

The only criticism that can be raised against this volume is that it comes into a field already crowded, without any very evident reason for its existence. It is a well put together, well-arranged, and, for the most part, well-illustrated book, which covers its field adequately and presents its subject-matter in a way attractive for students and authoritative for older men. The description and plates of Connell and Turk's modification of Maunsell method of end-to-end anastomosis of the intestine here makes its first appearance, we believe, in a text-book.

A Text-book of Clinical Anatomy. For Students and Practitioners. By Daniel N. Eisendrath, A.B., M.D., Clinical Professor of Anatomy in the Medical Department of the University of Illinois (College of Physicians and Surgeons); Attending Surgeon to the Cook County Hospital, Chicago, etc. Octavo, 515 pages. Illustrated with 153 illustrations, a number in colors. W. B. Saunders & Co., New York, Philadelphia and London.

The teaching of anatomy as usually done in our medical schools is deficient in that it is not sufficiently topographical in its nature. In taking up the bones, vascular system, muscles, etc., in groups, and considering them in this, the customary way, the student loses sight of all perspective and does not sufficiently correlate the knowledge he has been acquiring in sections. It is this defect the author has endeavored to bridge over by making his discussion of the subject purely regional, together with a completely new set of illustrations. These consist of photographs of living models on whom the various structures, superficial and deep, of medical and surgical importance are traced in their relations to each other, and the surface landmarks. The idea is excellently carried out and the text is equally original, so that the subject is given a freshness and interest likely to make it attractive both to the student and graduate.

Surgical Diseases of the Abdomen, With Special Reference to Diagnosis. By Richard Douglas, M.D., formerly Professor of Gynecology and Abdominal Surgery, Medical Department, Vanderbilt University, Nashville; Ex-President of the Southern Surgical and Gynecological Association, etc. P. Blakiston's Son & Co., Philadelphia.

In this eminently scientific work the physical diagnosis of abdominal conditions is discussed with an elaborateness probably never before attempted. But little attention is paid to operative technic or methods, the proper surgical procedure in each case being simply indicated, though occasional discussions on open questions involving the operative treatment and after-management are interpolated. The entire domain of the abdomen is covered in about one hundred sections devoted to the diseases and injuries of the various organs which in every case embody thoroughly modern and thoughtful views of the subjects in question. Gynecological conditions whose manifestations are chiefly abdominal are discussed with the exception of inflammatory lesions of the tubes, the rationale of which omission is not apparent. The various forms of internal herniæ receive adequate treatment, but the subject of strangulation of external herniæ, which also would seem to fall within the limits of a work on abdominal diagnosis is not elaborated.

The plates are well chosen and of an order of execution comporting well with the entire tone of the work, which both scholastically and mechanically is of the highest rank. It is essentially the outcome of the great advances which abdominal surgery has made within the past decade, and should command the attention of the profession everywhere.

A Text-book of Diseases of Women. By Barton Cooke Hirst, M.D., Professor of Obstetrics in the University of Pennsylvania; Gynecologist to the Howard, the Orthopedic, and the Philadelphia Hospitals. 8vo, 675 pages. Illustrated with 650 original illustrations, many in colors. W. B. Saunders & Co., New York, Philadelphia and London.

The appearance of this book will be welcomed by those who are familiar with the author's writings on obstetrics. In many respects, particularly in the number and beauty of the illustrations, it is a companion volume to the Text-book of Obstetrics. The same breadth of scope and thoroughness of treatment are present to a notable degree, and an agreeable style enlivened by many citations of personal experiences makes it enjoyable reading. An especially commendable feature is the unusually large number of illustrations devoted to microphotographs of pathological specimens, which are so clearly described as to be of real value. Office treatment is given a due amount of consideration, so that the work will be as useful to the non-operator as to the specialist, while the latter will find abundant food for thought in the section devoted to operative technic. Many innovations are contained in this, such as a new method of etherization, the use of Downe's electro-hemostatic clamps, a new method of employing rubber dam as a covering for the patient's abdomen during laparotomies, etc. In short, the book is an important addition to the already long list of gynecologies and deserves the consideration of all interested in this branch of surgery.

ORIGINAL ARTICLES.

THE SOCIAL EVIL IN UNIVERSITY LIFE: A TALK WITH THE STUDENTS OF THE UNIVERSITY OF PENNSYLVANIA.

BY ROBERT N. WILLSON, M.D.,
OF PHILADELPHIA.

I CONGRATULATE those of you, to-day, who are just entering this old University. Those who have already learned to call her alma mater need no word from me to tell them of the joys and responsibilities of college life. It is because some of us older college boys have learned just what you are to encounter in the four years of city and university experience, that we have called you together for a frank talk on matters that will have a vital influence on your college- and after-careers.

You will have guarding over your interests, and watching with a keen and kindly eye your successes and failures, one of the warmest hearted men that our Provost's chair has ever held. In the midst of responsibilities that would bend the shoulders of an ordinary man, you will find that he has a smile and a grasp of the hand for each one of you, no matter how unimportant you may consider yourself to be in your particular sphere of activity. He wishes you simply to assure him that you are active in that sphere. I have learned to know him as a man whose aim in life to-day is the genuine benefit and happiness of young men like you and me.

In close touch with your Provost, and equally a man, you will learn to know and love one of the best friends of my college days, and one who learns for the first time to-day, perhaps, that this influence was stronger than almost any other in making my college life of whatever value to myself and others it may chance to be. If he could but know how many men have left these walls with the same sentiment in their breasts, he would tell you, as I now do, that he has not lived in vain. I have seen Vice-Provost Smith in the midst of his day's work, stop as each of a number of thoughtless students pushed his way into the office, and show the same warm interest in the last one that sent the first away with the feeling that he had talked with a friend and one whom he could trust.

For myself, I can simply say that I have worked among you as one of your university physicians for over three years and that I have considered my work a rare privilege and a sacred trust. I have learned many things of student life which escaped me while a student myself; and I have learned the value, during these thirteen years of college associations, of the opportunity of looking on many of the problems that will soon come before you. Perhaps they mean more to me because I have seen many of them both from the standpoint of the student and later as your confidential medical friend.

One of these problems involves a temptation that meets every man sooner or later, will certainly meet you during your college days, and perhaps has already stood in the path of some. I refer to the temptation to risk your health of mind and body by illicit intercourse with women, whom you would be unwilling and even horrified to consider of the same order of being as your mothers or your future wives. Every large city swarms with such women, nearly all of whose lives are wrecked by marital infidelity before they begin to prey upon the happiness of other homes.

Shall I tell you in another way why you are gathered here to-day? Last spring a country boy came to Philadelphia for the first time. He was induced by friends to visit a house of ill fame. He was infected by the woman with gonorrhea, and, though at the time none of the ordinary symptoms appeared, in a day or so his eyes began to smart. Another of his so-called friends advised him in all earnest to wash his eyes in his own urine. He did this at once. Gonorrheal inflammation developed, probably had developed before the urine made the infection sure, and to-day that country boy is totally blind and for his lifetime.

Your Provost and Vice-Provost have watched with increasing interest and alarm the influence upon those who have gone before you of the temptations offered by university life in a great city. They have asked me to talk to you to-day of this matter as one of the students' physicians, and, therefore, one who ought, and, I am glad to say, does, hold intimate and strictly confidential relations with every one of you that cares to use me as an adviser and friend.

In the last three years of my work among the students of this University I have seen you at times and under conditions, that have led you to open your hearts to me; whether always through friendship or necessity it is at present unnecessary for me to inquire. I have seen many of you at times when you would have given worlds had someone told you in advance of the facts which I hope to make plain to you to-day. I have listened, more regretfully on each occasion, to the old cry, "Why did not someone tell me in time?" until it seemed impossible that another year should be allowed to slip by without giving those who are coming on the warning of the experience of those who have gone before. I have seen some of you injured physically, and for life, by either the lack of some such frank, clear discussion of the dangers of impure living, or by wil-

ful disregard of advice in the few instances in which it had been offered.

In my capacity as university physician, therefore, and one who holds himself ready to serve you at any time, day or night, I wish to talk briefly but earnestly of two of the almost inevitable results of impure sexual life. I have said that the opportunity of lowering yourselves in the eyes of God and of true men will certainly be presented to you within the nearest future. In a large city this is unfortunately and peculiarly true. Example, fear of ridicule, or curiosity may be the impelling force; and if any one influence has had a dastardly effect upon the lives of young men, ridicule is that one. Whatever or whoever you are we are interested in you, and want you to know to-day and finally that you transgress the laws of pure sexual living at your peril, and perhaps literally, sooner or later, at the cost of your life.

It may be stated with the barest possibility of error that no man who has once had sexual intercourse with a woman not his wife, fails to make a habit of the crime. It is equally certain that no one has ever indulged in such excesses without sooner or later contracting some venereal disease. This is so literally true that such conditions are considered among medical men as inevitable attendants upon impure intercourse with the other sex. Every preventive has been tried and all have failed. On the other hand, let me say to you as a physician voicing the consensus of medical opinion, that there has never existed a man who could not live a healthy, active existence, throughout his whole life, in the absence of any sexual intercourse whatsoever. It is a common story among college students that after a certain age a man requires sexual satisfaction, if he is to preserve vigor of mind and body. Let me characterize this idea as a curse that has done more harm in the home-world than any other influence, and one which, together with ignorance of the inevitable results in the way of venereal infection, has made it unsafe for men and women to drink out of a neighbor's glass, or for men to accept a pipe, or a cigar, or a cigarette, from the fingers of a friend unless they know him through and through in a way that few men are known. Nature has provided for man's sexual necessities in a way, with regard to which you do not need to be informed, and that provision is one that is as ample as it is providential. If, in addition, a boy has a wise father, who remembers his own temptations, and takes a judicious and the only fair way of strengthening his son against them, by opening his eyes to the danger of transgressing Nature's laws, he is well equipped for growth into noble and healthy manhood. Would that every boy had such a father! Too often the whole subject is treated in open conversation as a necessary and unavoidable evil. We should look upon the man or woman who trifles with the subject of sexual impurity as a criminal either by virtue of ignorance or by intent, and we will even then not reward them as they deserve. We have come to a time when, if the young men of this and other countries do not engage and conquer the social evil, it must be accomplished by the enlightenment of the pure women that still exist: and when your mothers, and your future wives, and your daughters, are warned even against their sons, husbands, and fathers, because they are dangers to humanity, you will begin to regret that you did not lay hold on the cause in time. The trend of the law is in this direction, and by the nature of things it is bound to insist upon it sooner or later. Lincoln is said to have made the remark that "every man who contemplated marriage should stand over the doctor with a club and make him tell the truth in reference to the chosen partner for life. Also that the parents who would allow a girl to marry a man without knowing as clearly as could be known his physical as well as his moral condition, deserved to be scalped." Unfortunately, no one is in a position, as yet, to know these things certainly, and no woman will believe them of her lover. Yet men have married women the day after lying with a common prostitute, and days, and weeks, and months after, syphilis or gonorrhea has appeared in the man, who invariably has been ignorant or cowardly enough to transmit the disease to his wife rather than acknowledge his condition. Many another man has struggled for months toward a cure and has been pronounced well by his physician, only to infect his wife with his latent disease. Add to this the fact that the average physician is unqualified to treat gonorrhea and syphilis successfully, and should not attempt the task, and you will learn how helpless the victim of such a disease is. In all this great city there is hardly a hospital bed that will admit openly, and as such, a subject of venereal disease. There is a tremendous duty to-day upon physicians and parents to learn and disseminate the truth in regard to sexual sin and my conscience will be clearer when I have spoken to you. Let me talk to you now of two conditions, gonorrhea and syphilis, the two most frequent attendants upon harlotry, and two diseases that are far more contagious and widespread than tuberculosis, which is occupying the attention of the public to-day. At the end of our discussion I trust I may have proved assertions which may seem to you at first both harsh and extreme.

GONORRHEA.

It may be a significant fact to you that the first student treated by me after my appointment as student's physician, and the last one seen at the close of the session of 1902-3, were suffering from gonorrhea, contracted during illicit intercourse with a woman. Both of these were sons of refined, well-to-do fathers and mothers. Both of them were ignorant of the imminent danger of infection, and both quoted the oft-heard lie, that "a case of gonorrhea is no worse than a bad cold." Both men had been told this lie by other students, who had themselves previously contracted and suffered from the dis-

case. One had repeated attacks before consulting me, and was then in a serious condition. One of these students is apparently well to-day. The former will carry traces of his gonorrhea to his grave and can never be the father of a child. He should certainly never marry, both for this reason, and for fear of infecting his wife.

During the three intervening years between these two cases, a number of students have consulted me each month, and many with the same story of ignorance of danger. All knew, no doubt, but few realized the fact until too late. Some few, through despair of being cured of a chronic condition, had thrown precaution to the winds, and contracted new infection and new trouble. In one instance that came under my care, a woman, herself a medical student at another institution, had infected five men with gonorrhea, and one of them either she or some other had also infected with syphilis. Two of these men were brothers, yet it would appear that none of the five had confided in any of the rest.

It seems strange that it should not be generally known by students that there is little likelihood of a woman, who admits of such attentions, herself escaping venereal infection, no matter what her social status or what her precautions. It is a rule borne out by medical experience, that a woman who will encourage the advances of one man will invariably do the same with others. It is also a frequent experience for a number of men separately to consult a physician, and assure him that the subject of their attentions could not possibly have infected them as she had never had intercourse with any other man, and yet the facts appear clear to the physician that she had infected each and every one. It is safe to say that every harlot (I use this term advisedly, with reference to her of good family connections, for there are such, as well as the common prostitute; they belong in the same category) has at some time been infected with gonorrhea; and if one stops to learn how difficult and rare a thing it is to thoroughly cure a woman of gonorrhea, he will understand also how dangerous it is to trust himself at any time in her subsequent life within her infected presence.

A few statistics may serve as an illustration, not only of the prevalence of temptation on the streets of a great city, but of the ubiquity of gonorrheal disease in its many forms. It has been well characterized as the most widespread of all contagious diseases, with the single exception of measles. It has been shown that in some of the cities of Europe more than one-half of the entire population, and more than three-quarters of the male population, suffers from gonorrheal infection. Dr. Allen reports from one hospital dispensary in New York City 86,000 cases of all kinds treated in 1900, of which over 3,000 were cases of venereal disease. In 1903 we learn from a commission appointed to study the subject that there are in New York City to-day about 200,000 syphilitic subjects, and probably four times as many (800,000) cases of gonorrhea. To care for these cases and to prevent the spread of infection, there is one bed for every 5,000 cases. This ratio holds good for nearly all the large cities of America. While all prostitutes are considered gonorrheic subjects, it is estimated that every fourth one is qualified to transmit syphilis. In Prussia it is estimated that there are annually 773,000 cases of venereal disease. Still more exact are the following figures: Out of 1,155 patients recently reported as treated at Hot Springs, Arkansas, and coming from all over the United States, it was learned that 818 (70 per cent.) had at the time of examination, or had had gonorrhea; 337 had never contracted the infection. Most of these patients were from the so-called better classes. The ages at which the gonorrhea was contracted varied from ten to fifty-seven years, averaging 21.8 years. Three hundred and eighty-two cases were below twenty-one years of age, and 58 cases were below seventeen years. Of 60,000 sick soldiers in our army of occupation in the Philippines 10,000 were cases of venereal disease; nearly all of these have since come home, and many remain uncured to-day.

These figures will suffice to show that gonorrhea is so frequent a condition that it literally leaves few homes unscathed, if the truth be fully known. As already stated the prostitute offers a ready infection to the male urethra in its virgin state, and a still more likely one to a chronically inflamed mucous membrane. Probably she can and does infect as long as she lives, and undoubtedly she does infect many men in one day. Long after she is visibly cured she may be a source of virulent infection. The result is that she may be honest in believing herself free from danger to others, and become the more dangerous in the belief of her cure. Under the most benign circumstances she is a danger, and under the worst she is a scourge. Infected many times, with each new occasion she becomes freshly virulent. The result is that the world is to-day overrun with venereal disease.

Let me ask a few questions that naturally arise; and in their answers endeavor to emphasize the points I wish to bring home to you.

What is gonorrhea in the male subject? An extremely infectious disease, usually involving some portion or all of the urinary passage from the bladder outward. Any portion of the body may, however, be infected, including the eyes, the skin, the nose, ears, mouth, bowel, and any or all of the internal organs. Its minimum average duration is six weeks. It often lasts for years, and unless promptly and intelligently treated, its effects often remain evident for life. It is a disease for which eminent specialists are constantly seeking some new and effective remedy, which has not yet been found. The question is still under discussion whether either syphilis or gonorrhea is certainly curable. One prominent student of the subject says of the latter "I have studied and treated gonorrhea for fifteen years, and I feel to-day that I know less about that disease than I thought I did several years ago." Another writes

"A large number of chronic gonorrheas, speaking generally, remain uncured. Some of these may be explained by the indolence and discouragement of the patient, others by want of care or understanding on the part of the physician, others by constant reinfection, and still others from no tangible cause, all gonococci having 'apparently' been eliminated." Still another says "the importance of gonorrhea with that of syphilis is 100 to 1, not only from the standpoint of the number of persons attacked, but also from the standpoint of the gravity of the lesions and their perpetuity."

Have I said enough to prove to you that gonorrhea is "worse than a bad cold"?

What are its possible complications and their frequency? Among the most frequent of the complications of gonorrhea are stricture of the urinary passages and sometimes even of the bowel, inflammation and destruction of the internal genital apparatus (the testicles and the tubes leading thereto), blindness, bladder and kidney disease, abscess at any point in the body, and joint rheumatism—all frequent conditions. Less frequent are septic blood infection (usually fatal), brain disease, degeneration of the spinal cord, heart disease, bone disease, peritonitis, pneumonia, and death. You may ask "Why have we not heard before of the serious features of what we believed to be a temporary inflammation?" I answer "Because every case of gonorrheal infection is concealed more jealously than a crime would be, and, if serious complications follow, the specific origin is denied or withheld by both the victim and his doctor." Last winter an officer of the University showed his interest in one of the students by calling on him in the University Hospital, and was told by the student and by the nurse that the trouble was appendicitis, and was shocked and disgusted later on when he was told that the case was one of gonorrhea.

A large percentage of cases of chronic gonorrhea leave behind a stricture of the urethra. Nearly all leave an irritable and often a diseased prostate gland, many leave an irritable or diseased bladder. Between 10 and 20 per cent. of all cases of infantile blindness are due to gonorrheal infection. Statistics of the German Empire for 1894 showed that 80 per cent. of all children born with healthy eyes who became blind, did so as the result of transmitted gonorrhea. In that country there are 30,000 cases of blindness to-day due to gonorrhea, and mostly transmitted from other persons. In spite of all the latest knowledge and the newest methods, approximately 600 cases of blindness occur annually in Germany from this one avoidable cause.

In this country from 25 to 50 per cent. of the blind in institutions owe their loss of sight to gonorrheal infection. In one year in New York City 136 cases of gonorrheal ophthalmia were reported.

Inflammation of the epididymis (the tube from the testicle outward) is a very frequent complication, often resulting in absolute sterility, as will be shown later. Gonorrheal rheumatism is also a serious affection, usually occurring in a large joint like the hip or knee, and frequently leaving a permanent disability. The other complications mentioned occur with varying frequency, depending upon the attention paid to the condition by doctor and patient as well as upon the promptness with which the disease yields to treatment. While far less frequent they are even more serious. There is no question that many cases of kidney disease owe their origin to gonorrhea, many resulting years after in fatality. During each year a number of deaths are recorded as directly due to infection by the gonococcus of one of the vital organs of the body. While writing this statement I have before me the records of five fatal cases that have come easily to my notice, three from gonorrheal peritonitis, one from gonorrheal valvular disease of the heart, and one of gonorrheal septicemia which will be mentioned later.

Can gonorrhea be cured, and can the patient be sure he is cured? To the first question probably "yes," and to the second certainly "no." We have already heard the doubtful statements of eminent students of the disease. Neisser, one of the first authorities in the world on venereal disease, claims that gonorrhea can be cured. Your own professors of surgery, White and Martin, also claim that it can. All admit that very many cases are *not* cured, owing to one reason and another. Every year brings forward new instances of old, supposedly cured infection relighted by disease, debility or debauch. In children, undoubtedly, the prognosis is better than in adults, probably because the disease is taken in hand earlier and more systematically; also because all the tissues in the child tend toward healthy growth. Frank in Germany has shown, however, that the gonococcus may remain quiescent in the prostate gland for months and years. No symptoms remain, yet the disease may be relighted and others be infected. I have already quoted Van der Poel to the effect that a large number of chronic gonorrheas remain uncured. Köppen cites many cases in which all symptoms had disappeared, and yet the disease remained latent. In regard to one of these he says: "Not one sign was left of a previous gonorrhea." Six years later there was irritation in the urethra, and he obtained gonococci from the urinary canal. In another case none of the germs of gonorrhea had ever been discovered in the discharge, though the clinical picture was complete. Six years later he found gonococci in the urethra. He concludes his article with the statement, "Gonococci can exist for years in the organism, as proved by numberless cases." A case is described in one of our own medical journals, dated September, 1903, in which a man infected his own eye with gonorrhea after six years during which the disease appeared to be cured. At the same time all his joints became involved, as well as the tendon sheaths of one foot. The gonococcus was obtained from

the discharges of the eye, proving the real nature of the infection. Our answer to the question, then, must be that under favorable circumstances gonorrhea probably can be cured. No case is cured until all gonococci have disappeared from the urethra. Many doctors either do not know how or do not take the trouble to look for these micro-organisms. Many patients never return for completion of the cure, after the symptoms have become tolerable. Under the best treatment, it should be remembered, success may not be attained. Only time will show whether an actual and permanent cure has been secured. No victim of gonorrhea can be absolutely sure, when the symptoms have disappeared, that he is cured of his infection or that he will not infect his wife years after.

How long after an attack can a man infect a woman with gonorrhea? We have already seen in our answer to the preceding question that years may pass by and a man may still be infectious to a wife. As long as there are active symptoms, transmission of the disease is likely. When these have subsided the danger decreases, but never disappears until the last gonococcus has been destroyed. If gonococci can live six, ten and fifteen years in the organs of the body, as they have been shown to do, probably they can live longer, and to an almost indefinite time. The only inference from the cases cited is that the gonorrheic subject must never be surprised if he finds in after years that his disease has remained latent, and that he has infected some innocent person. The possibility is always before him.

What are the possible and permanent injuries from an attack of gonorrhea? We will at present consider only the male sex. It has already been shown that fatality is occasional. The most frequent permanent disability is a chronic gleet or catarrh of the urethra, prostate gland, the bladder, or all three. Such a chronic inflammation of the urethra usually results in stricture of that passage. Stricture causes obstruction to the flow of urine, and as a consequence bladder inflammation often follows, and the disease often spreads from there to the kidney by direct extension. Gonorrheal rheumatism very frequently, we may say nearly always, leaves a crippled joint.

By far the most serious sequela of gonorrhea is sterility, or lack of power to produce progeny. The commission appointed by the American Medical Association estimated that 42 per cent. of all gonorrheic subjects become sterile, and that many more cause sterile marriages after the first childbirth because of the infection and consequent sterility of the wife. Czerny says that "50 per cent. of all sterility is due to the husband's gonorrhea." Morrow says "syphilis curses the child; gonorrhea prevents its existence by rendering the male sterile."

President Roosevelt has recently spoken of the social evil, meaning the wilful sterility of the wedded life. Would that he might cry out from his presidential chair against the dangers of venereal infection and the real cause of sterility of the sons of America.

What are the results of gonorrhea in the woman? Fewer women, by far, are cured of gonorrhea than is the case with man. I shall not speak, however, of the clinical picture in the female sex. It will be sufficient to say that with the woman gonorrhea means almost certainly an infection of her internal organs, and sooner or later a serious operation. Pregnancy increases the danger of upward and general infection. Sometimes there is no serious sign of trouble until the woman becomes pregnant. Nöggerath states that 50 per cent. of sterile women, owe their sterility to gonorrhea. Neisser, already quoted, fixes the percentage at a higher figure. Ascher found that of 227 sterile women in his care 121 were sterile owing to gonorrhea. Sänger says that abortion occurs as frequently owing to gonorrhea as it does as the result of syphilis. Nöggerath cites the cases of 53 women, pregnant during a gonorrhea, of whom 19 aborted. Frühingsholtz cites 101 cases, of which 23 aborted, and 7 went into premature labor. Price of this city says that of 1,000 abdominal operations in women 95 per cent. were the result of conditions due to gonorrhea. The statistics of the German Empire for 1894 showed that 80 per cent. of the women who died of uterine or ovarian disease died as the result of conditions dependent upon gonorrhea.

Have I convinced you yet that the disease is of more significance than a "bad cold?" If not let me add a final argument and if you resist the plea of the children no influence on earth can save you from an experience which you dearly earn.

Can gonorrhea be transmitted to others than your wife? From what I have already told you, you now know that the vast number of cases of gonorrhea in the woman in married life are instances of innocent infection on her part. We have omitted until now the possibility of infecting others, and by means other than by sexual intercourse. First, and least important, by all odds, you can infect your own eyes, nose, mouth, or bowel, and probably will unless you learn the virulence of the gonorrheal germ. Next you can infect, and usually do infect, the bedclothes, towels, napkins, handkerchiefs, knives, forks, your pipe, and all articles of ordinary and constant use, and sometimes, by means of them, your wife and children, your friends, even, mayhap, your mother. It is the result of nature's protecting laws and not your care that you fail to pass to all who are around you the curse that you have brought upon yourself. Let me prove this to you in all its hideousness of truth. Cook has reported recently a case of a four-year-old daughter of a thirty-five-year-old father, from a refined family. The father contracted gonorrhea in the usual manner, and soon the little girl developed the disease. There was absolutely no other traceable source of the infection. Morrow cites the case of a little girl into whose eye a playmate's finger had been poked. The injured child suf-

fered a typical gonorrheal conjunctivitis, from the discharge of which the gonococci were obtained. Not long ago there was an epidemic of gonorrhea among the children of Posen in Germany. In two weeks 236 children contracted the disease, which was finally traced to the use of the public bath. Someone had infected the pool. In spite of the constant suppression of such cases there are many such reported in the medical journals. I have myself seen in hospital work many cases of gonorrhea in children under five years, sometimes transmitted by accident, sometimes by intention. Only when the law imposes a fine and imprisonment upon him who knowingly infects another person will this crime be blotted out; it may be that a sterner penalty still might be effective (as already suggested) and meted out at the hand of the surgeon's knife. Innocent infection of children occurs usually among those who sleep in bed with their parents or use the same towels or table linen. Night clothes, bed linen, towels, sponges, underclothing, soap, the water closet,—if once infected, may retain the germs for weeks and months, and the origin of the infection may, sad to say, never be discovered. On the Scandinavian peninsula every case of venereal infection is reported to the authorities, as it will be some day here. There will then be fewer cases of venereal disease, and fewer innocent victims. I believe, moreover, that in this procedure lies the remedy for marital infidelity, and for sexual sin in all its forms.

There is another serious phase to the gonorrhea of children. When once infected they also transmit the disease, and oftentimes in the same manner as their fathers, and with equal avidity Wolbarst, in New York City, cites 22 cases occurring in his work during two years, in children between eighteen months and twelve years of age. The usual mode of infection was attempted sexual intercourse. On investigation he found that it was by no means an uncommon thing in this district for children not yet in puberty to indulge in sexual intercourse. He saw three cases of boys, four, ten, and twelve years respectively, infected by girls between ten and twelve years. Many other cases were due to the child sleeping with parents, brothers, sisters, who had gonorrhea. Cotton calls attention to a "string of little girls coming to my clinic suffering from gonorrhea. A week later," he says, "my assistant brought a boy of ten years who had been infecting these little girls." Last year I saw more than one student of this University who would not return home for his holiday, when he heard that he must be careful not to infect himself or his family. I shall never forget the expression of one who said "God! you don't mean that I might give this to my mother."

Boys, forget yourselves! If you owe anything to that mother, sister, perhaps some day a wife, your children, your friends, servants, even the laundry woman,—do not risk this disease!

Just a word as to *the mortality of gonorrhea.* This is occasional, though by no means as high as that of syphilis. Only last year there came to my notice the case of a young man, dying from a diffuse abscess and pyemia (blood poisoning) of unknown cause. His life was pledged to a lovely girl, who nursed him on the edge of his grave. Both were of our nation's best blood. Cultures from the pus of his abscess and from his blood showed colonies of the gonococcus, and a history of an almost forgotten attack of gonorrhea was obtained. It is almost too horrible to think of the crime of the future had he lived to marry the woman who was nursing him in an ignorance of the cause of their double sorrow as complete as his own.

Such a tragedy is being enacted certainly many times every year in this wide world, and bids fair to become an even more frequent occurrence. I have mentioned four other deaths to you. The aggregate of deaths from the sequelæ and complications of gonorrhea amounts to no small total, and must soon attract the attention of those who have heretofore looked on the disease as a passing ailment.

Have I made plain to you that as the result of one rash act

Your wife may be a lifelong victim,
- may be deprived of the power of conception,
- may lose her life by an operation or by infection.

Your child may lose its chance of birth,
- may, if born, be deprived of sight, or hearing,
- may, if a male, suffer consequences equal to your own; if a female, suffer like the mother.

Yourself may never be cured,
- may infect those who are dearest to you,
- may lose your own life and those of others.

Let us now for a brief moment consider syphilis.

SYPHILIS.

Probably far less need be said to you about this disease, as its name is known to most of you, and few speak of it lightly. When you learn that many of those who surround you in your daily life are virulent with this disease, and that changeling children are born into our best families as the result of it, and that prostitution is likely to fix the unyielding grasp of syphilis upon you, it may act as a persuasive to keep you true to your ideals.

What is syphilis? It is an infectious disease of the whole system, usually making itself first known by means of what is called a chancre, or initial sore. This is followed usually by a general skin eruption, swelling of the glands, falling of the hair on all parts of the body, and later on by serious disease of the blood vessels and internal organs. It is usually contracted during sexual intercourse; in the case of men, usually in prostitution; in the case of women very fre-

quently in an innocent manner and in wedlock. It involves a course of treatment of at least three years, and sometimes resists all treatment. It is found in the highest and lowest classes of society.

How prevalent is the disease? Fournier states that one seventh of the population of Paris is syphilitic, while in Russia whole towns have been decimated by the disease. The victims in the latter country are mainly women and children, and many cases are due to the kissing of sacred images and to the embraces of syphilitic acquaintances. In certain of the European countries 25 per cent. of the population of some of the villages is syphilitic, in most instances due to innocent infection, prostitution being almost unknown. China and Japan are overrun with syphilis. It has been estimated (Dictionary of Statistics, Mulhall) from the cases in the military hospitals in Europe that between 7 and 43 per cent. of the entire soldiery is infected. The average national percentage was found to be 14 per cent. The report of the American Dermatological Society finds that 11.5 per cent. of all skin diseases are syphilitic. And in our own country again. Out of 1,485 cases of all kinds treated and questioned at Hot Springs, Arkansas, in 1901, 831 had had syphilis. Gihon estimates that there are 2,000,000 cases of the disease constantly in the United States.

Sänger has shown that nearly one-half of all the prostitutes in New York City freely admit that they have had syphilis, and half of these gave birth to syphilitic children. And as a gloomy shroud for all of these figures, Morrow finds that 70 per cent. of the syphilis in the women of New York City is the result of conjugal infidelity.

Can syphilis be cured? This is a far more difficult question to answer than that with regard to gonorrhea. My personal belief is that it usually can, if well treated and in time. A cure, under the most favorable circumstances requires at least three years of constant medication. Many cases require a longer time. Some prominent syphilologists declare that the disease is incurable. Certain cases are absolutely incurable. Among these may be cited one reported recently by Schamberg, which was under treatment without success for eight years and two malignant cases reported by Fournier in 1899. The general prognosis of syphilis is probably a good one. The constant danger that the treatment has not been radical or thorough enough always threatens, however, and is well expressed by Osler when he speaks of "the extraordinary frequency of the cerebral and other complications in persons who have had the disease, and who may even have undergone thorough treatment." Howard has reported a case seemingly cured and relighted, after a year of quiescence, by influenza. Many other cases appear to be free from symptoms for a time, and then die of insanity, softening of the brain, locomotor ataxia, or some other nervous disease.

How long after infection can the disease be transmitted to others? During the entire period of what are called the primary and secondary stages. The latter, if the disease has been thoroughly and conscientiously treated, is usually confined to the first few years following the infection. Only in exceedingly rare instances has infection taken place after the fifth or sixth year. Such cases do, however, occur. Sack reported last year the case of a man on whose person appeared an ulcer (gummatous) ten years after the original infection, and infected his young wife, who displayed typical symptoms of a new syphilitic infection. Six months later she also had a miscarriage. Herscher reports a case of contagion from a husband who unquestionably contracted the disease thirteen years previously. Kopelinski has reported two cases of inherited syphilis infecting previously healthy individuals, in both instances a grandmother (an almost unheard-of thing).

What are the effects of syphilitic infection upon the man? Perhaps the most serious is the fact that he becomes at once a source of danger to his family, friends, and society in general. This begets the next most serious influence which is the mental condition. Fournier cites 18 cases of suicide in young syphilitics. We have already sketched the course of the disease itself, and need not repeat the symptoms here. Probably the most serious physical damage is done the blood vessels and kidneys. Many a case of apoplexy and aenurism is directly due to syphilitic change in the arteries of the brain or elsewhere. Many cases of insanity are also due to this disease. At present there is an attempt to prove what many authorities believe to be true, that locomotor ataxia is purely and simply a syphilitic picture. Many cases of syphilis become and remain completely bald, with no eyebrows, and no facial hair. Some few severe cases lose all the bony features of the face, the nose and roof of the mouth undergoing complete necrosis (bony gangrene). Many have a persistent skin eruption. Those who inherit syphilis are usually marked for life, and die at an early age. Tuberculosis frequently accompanies or follows syphilis, like the driver of a hearse.

What are the effects of syphilis upon the woman? The physical effects are the same as those in the man. If she bears children during the course of the disease they are likely to be syphilitic and otherwise defective. Even more likely will they be stillborn, or abortion take place. There is no other cause of abortion that compares with the vicious influence of this disease.

A syphilitic woman is likely to infect many more persons than is a man. If a prostitute, she probably infects most of those with whom she has intercourse. Even in everyday life a syphilitic woman is a source of great danger. Woman's habit of indiscriminate kissing is the most prolific source of transmission next to sexual congress, and especially in this country, where men confine their embraces to their intimates only and to the female sex, unless it be in the case of

children. A woman's embraces are much more promiscuous, and she proves much the more active in spreading the disease.

What are the effects of syphilis upon the offspring? These are two and both are serious in the extreme. First a tremendous percentage of the children born of syphilitic parentage are deficient mentally and physically. Secondly, between 20 and 40 per cent. of all conceptions by a syphilitic woman result in either abortion, stillbirth, or premature labor. Even if born with a competent mind, the child who has inherited syphilis is cursed as Job was not. It is likely to die before it reaches puberty, and is generally marked so as to be an object of pity throughout its life to itself as well as to those who know the cause.

How can syphilis be transmitted? By contact with a syphilitic sore during the primary and secondary stages of the disease, also with the blood, with the saliva, or any fluid that may carry with it the discharges from a mucous patch or other syphilitic lesion, etc. Usually the infection is transmitted during sexual intercourse, though extragenital and innocent infections are now recognized to be very frequent, as by means of knives, forks, spoons, drinking glasses, pipes, cigars, etc. Kissing, as has already been stated, is one of the most frequent methods of contagion. There is danger in any abraded surface upon the body when in company with a syphilitic in the infectious stages of the disease. A mother may infect a baby, a baby may infect a nurse, the father may infect the whole family. Weitlander has reported within the last three weeks two instances of infection of entire families, in each case by a small child, known to be syphilitic, who was taken in to board. The infection undoubtedly took place by means of spoons, dishes, etc. If any warning given at this time will take root in the minds of those who are unfortunate enough to have contracted the disease innocently, and to have extragenital sores upon their body, it must be this, that such cases are the most dangerous to mankind. The very irony of this fact makes it the more pitiful, and the crime of the original infection the greater. I do not think I need emphasize the burden of the cry of the infected one, who would warn each of you from the possibility of becoming a danger to your family, your doctor, and all around you.

What is the mortality of syphilis? In England in the period 1880-90 1,742 males over five years of age died from the disease. Whole towns have been decimated in Russia. Last year in Philadelphia there were 37 deaths registered as due directly to syphilis. If we add the many deaths due to apoplexy directly dependent upon syphilitic arteries, or to other more obscure syphilitic conditions, the total would in all likelihood be an appalling one. It is sufficient to say that there is a decided mortality as the direct result of the disease and its complications that cannot be overlooked. The secondary mortality has recently been brought home in a most impressive way by Fournier, a French physician, already quoted, who has collected 18 cases of suicide directly or indirectly dependent upon the knowledge of the patient that he had syphilis.

Let us now gather together the lines of our talk. I have told you many of the consequences of gonorrheal disease. I have purposely said much less of syphilis. Other venereal infections I have entirely passed by. May I now fairly ask for your decision in regard to certain questions which I put to you earlier in the day? Is prostitution worth while? Is it safe? Do you dare to run the risk? Have I said enough to sufficiently warn without rendering you callous through overtalking? If so, I shall welcome the day when your Provost asked me to work among you as student's physician. There are those who make light of the social crime; and you now know why I shudder when I hear them trifle about a subject the gravity of which they know nothing. I have recently read a book by one of the prominent literary women of the day, as full of vile insinuation, and as wicked in its flagrant discussion of man's and woman's infidelity as if she had never heard of a wrecked home or life. The story itself was of a social crime, and was read with avidity by the unthinking public. Perhaps you have all read it.

This very summer there appeared a book, which I found on my library table, loaned by a "friend" to my wife. Its central figures were separated by the crime of the age, and, though lovers indeed, could not marry. There were three other marriages prominently introduced into the story, and two of these were blighted by infidelity of one or the other party. I read this book because the author—this time a man—had written other books of surpassing beauty and brilliancy of thought and theme. If such books influence others as they do me their authors must shoulder the responsibility for many a mental and moral downward plunge, and only after an effort a struggle upward. God forgive anyone, I say, who dares urge a man, and above all, a young unmarried man, to trifle with the purity of sexual relations as these writers have presumed to do.

And now one last word to a body of men that will one day take part in the destiny of this country. I have carefully avoided telling you that you owe the sterling purity of mind, soul, and body, to your God and Maker. I trust that someone else may do this in the near future and in this same old Chapel—whose benches already hold the sons of fathers who have gone before. I would not have you forget the fact that God has made for your use a body that is more wonderful and delicate in its mechanism than any invention of human genius, and that in your power of raising up children after you who may do Him honor He has given you control of a mystery that no scientist has been permitted to unfold. Use this gift nobly and well; and in order to do this thing, guard your purity of thought and action as jealously as you would on the day that you bind yourself, for life and death, to the wife.

whom God gives you in the place of your mother. You owe to her and to your children a perfect moral and physical legacy.

CASE OF MASTOIDITIS; SINUS THROMBOSIS; PYEMIA; TWO OPERATIONS; RECOVERY.*

BY THOMAS R. POOLEY, M.D.,
OF NEW YORK.

RECOVERY in a case of marked pyemia from any cause is certainly well worth reporting. It is this consideration, as well as many other interesting features, that has led me to report the following one.

The patient, Jennie Gallagher, a stout Irish girl of twenty-five years, came to the clinic of the New Amsterdam Eye and Ear Hospital on March 7, 1903, with the following history: Five weeks ago her sister had died of puerperal septicemia and she was in constant attendance upon her until she died. Two weeks ago she was taken ill with the grip and three days thereafter developed some earache on the left side. The same night there was rupture of the membrana tympani and a free discharge took place. Upon admission to the hospital there was a profuse discharge and a perforation in the anterior inferior quadrant of the membrana tympani, marked pain and tenderness with distinct redness and swelling. The swelling was confined to the mastoid region, did not extend upward and backward toward the site of exit of the mastoid vein, nor to the upper portion of the cervical triangle. The discharge showed abundant evidence of the presence of stereptococci. The appearance of the patient was that of profound infection; temperature 101⅘° F.; pulse 120; respirations 30. Immediate operation was advised, at once consented to and done the same afternoon with the assistance of Drs. Claiborne, Barstow and Cook, and in the presence of many others, the patient being under ether.

The usual Schwartze's operation was done. The whole of the outer table was found to be softened, necrotic, and the cells filled with dark blood and granulations. The entire cortex was removed to the tip. Upon making an attempt to open the antrum with the rongeur, the sinus, the position of which was abnormally far forward and its wall extremely thin from caries, was accidentally opened, giving rise to a profuse hemorrhage. A tampon was quickly inserted and the hemorrhage promptly arrested. A posterior flap was now made to give better access to the sinus, when a small discolored point was seen upon the sigmoid roof. This necrotic opening was gradually enlarged by means of the curette and the rongeur, exposing the descending portion of the sinus for nearly its entire length. The plug was then removed from the sinus and a new one inserted. The antrum and mastoid were packed with iodoform gauze. The upper parts of the flap were brought together with silk and catgut sutures and a bandage was applied. The patient bore the operation well.

On the following day the temperature dropped to normal, the pain had ceased, and the entire condition was satisfactory. On March 10 the dressings were removed. There was no suppuration, the wound looked aseptic; the plug was removed from the sinus, no hemorrhage took place; temperature 100° F.; pulse 86; respirations 28.

The wound was dressed again on March 12. The temperature had risen to 100.4° F. On removing the gauze it was found that the wound was sloughy, the periosteum was detached from the bone, and there was a profuse, offensive discharge from the wound. The exposed sinus was cleansed and the gauze reinserted.

On the two following days the wound had about the same appearance, but distinct redness

*Read by title before the American Otological Society, Washington.

and tenderness in the course of the jugular and an acute tonsillitis had developed. The patient complained very much of pain from this and of aching all over. On March 15 a very painful arthritis of the middle finger of the right hand had developed. The wound was dressed and there were suppuration and a gangrenous appearance of the posterior flap; temperature 103° F.

On March 16 the temperature was the same and the pulse was 120. On the night of March 16 she had a severe chill, with a temperature of 103.6° F.; pulse 130; respirations 36. Ophthalmoscopic examination revealed choked discs in both eyes. The diagnosis of septic thrombosis was made and another operation was proposed and performed on the afternoon of March 17 at four o'clock.

The original wound was opened up and another posterior flap higher up was made. All the remaining bone covering the sinus was removed by the rongeur, first in the direction of the torcular. The covering of the sinus was then slit with a pair of straight scissors in its long axis and was found to be filled with a firm fibrinous clot, which was removed with the sharp spoon and the blood current re-established in this direction, this part of the sinus being then plugged with iodoform gauze. The exploration was then continued in the descending portion of the sinus toward the jugular bulb, which was also found to be filled with a purulent, disorganized clot. This was removed and, as no blood current from the proximal end could be re-established and the curette carried into the jugular still continued to remove clots and pus, ligation of the jugular seemed to be imperatively demanded, but the patient's condition was such as to make us fear that she could not survive any further operative interference. The pulse was rapid (140 or more) and very feeble; the respirations were very frequent. It was therefore determined to make another effort to get the blood to flow through the jugular, which was finally accomplished by still further curetting of the jugular vein and by more or less forcible manipulations on the jugular vein and neck, by which means quite a quantity of blood streaked with pus escaped and then a free and copious hemorrhage took place. This method was resorted to with the full knowledge that it has been strongly condemned by excellent authority and because of my unwillingness to leave the obstruction and the assurances that the patient, who was almost moribund, could not survive any longer under the operation. The operation was now hastily terminated. No sutures were employed in the flap. The exposed dura was covered wth iodoform gauze, both ends of the sinus were plugged with the same, and a bandage was applied. The operation was completed at about 6:30 P.M. The pulse was so rapid and feeble that it could hardly be felt at the wrist. Hypodermics of whisky, ether and strychnine were given and a large high enema of normal salt solution. Hot-water bottles were applied to the surface of the body and friction made. Under this heroic treatment, after a number of injections, ⅙ of a grain of strychnine in all having been given, she was gradually resuscitated, but the pulse was still very frequent, about 140, and hardly perceptible. The temperature by rectum was 103° F. and by the following morning it was 102.2° F., with profuse perspiration. The next day the temperature ranged from 100.6° to 102° F.; pulse 90 to 102; respirations 38 to 42.

The patient was given whisky and strychnine by hypodermic injection until evening when she began to take whisky by mouth. She had several loose stools and slept but little. There was no disturbance of the sensorium. She complained of pain in both arm and hip and had some nausea but did not vomit.

On March 19 the wound was dressed. There was not much suppuration. Both plugs were removed; no hemorrhage followed. Temperature, pulse and respirations continued about the same. There was some stiffness and tenderness in the upper part of the cervical triangle, but no swelling and very little pain on pressure. She complained of pain in the right ankle which on inspection was found to be red and swollen. Hot whisky and liquid peptonoids were given.

On March 20 the temperature was still higher; pulse and respirations showed about the same variations. The patient took nourishment well. The ankle was still more painful, red and swollen. There was profuse perspiration. The patient slept a good deal and seemed stupid. There was involuntary passage of urine; the pulse was rapid but stronger. The wound discharged profusely.

On March 22 the patient complained of pain in the right shoulder which was tender to the touch. The temperature ranged about the same, with profuse perspiration. The ankle was still more swollen; a bichloride dressing was applied. On the next day she had a slight sensation of chilliness but no distinct chill, perspiring very profusely.

On March 24 the temperature rose very high, reaching 104.6° F.; pulse 131, respirations 52, and she complained of severe pain in the right side and back. On March 27 a careful examination of the lungs, made by Drs. Barstow and Bickerston, revealed the physical evidences of pneumonia over the right lung.

March 28, highest temperature 103.6° F. at 6 P.M.; highest pulse, 128; highest respiration, 148. Pain in the back very severe. Perspiring very freely.

March 29, highest temperature, 100.8° F. at 11 P.M.; pulse 120; respirations 48. No cough or expectoration.

April 1: Wound is gradually healing. Sinus, antrum and bulb gradually filling in. Dressed with balsam of Peru.

April 2, highest temperature, 103.6° F.; pulse 129; respiration 40. Restless, a little incoherent; perspiring freely; involuntary urination. Abscess in upper anterior part of arm opened. In dressing the wound, on removal of the gauze

from the bulb, a smart hemorrhage occurred which was only controlled by tight packing.

April 6, a very tender, indurated place over the left buttock; probable abscess forming. Abscess on the arm continues to discharge freely.

From this time on abscesses formed in the buttock, two more on the arm below the first; both were opened, as was also the one on the nates. The wound had gradually closed in the sinus and that in the antrum had entirely healed. There is a good deal of bare bone over the posterior part of the mastoid and the squamous portion of the temporal bone. The finger has healed with firm anchylosis of the joint, but the swelling of the ankle has entirely disappeared without any impairment of the joint. For the last two weeks the pulse and temperature have been very nearly normal, the highest being 99 or 100° F. in the twenty-four hours.

The patient is still bedridden, very weak and unable to raise her head from the pillow. The wound at both ends of the sinus is closed. There is still some uncovered bone in the posterior part of the mastoid and squamous portion of the temporal bone. The patient may be fairly said to be convalescent, but I reserve a full account of the case, with such remarks as I may wish to add for another time when the case has reached a final conclusion.

Since writing the above the condition of the patient has been one of very slow and tedious recovery, with a very slight rise of temperature in the afternoons, frequent sweatings, gradual diminution of the quantity of pus discharged from the abscesses until they finally healed, great exhaustion, irritability, and indisposition to help herself, not even lifting her head from the pillow until after April 26, when the temperature continued about normal throughout the twenty-four hours, and she gradually began to recover some degree of strength and sit up in bed a little while.

On May 29 the exposed bone was found to be loose and a large sequestrum was removed, leaving perfectly healthy granulations underneath. The sequestrum consisted of a portion of the mastoid and squamous portion of the temporal bone, the upper and posterior border 3 cm. long, irregularly serrated for articulation with the parietal bone, the inferior border 3 cm. long, irregular from marks of the rongeur, the anterior border irregular and notched, 1½ cm. long, the posterior border 8 mm. long and slightly irregular, the whole varying in thickness from ½ to 2 mm.; the inner surface irregularly concave and the external surface convex.

After removal of the sequestrum the healing progressed much more rapidly. On June 11 the patient was discharged, still in a very weak and emaciated condition, having been in the hospital for a little more than three months. There was still a small area of wound unhealed, but the sinus and antrum wounds had entirely healed. The right middle finger was flexed upon the hand and the metacarpal joint anchylosed. The temperature was normal, appetite good. There was gradual daily return of strength and only an obstinate constipation, which had existed all through her sickness to contend with.

On June 27 I last saw the patient at her home, having been called to see her because she had suffered for the past two nights with headache and flashes of light before the left eye and a piece of bare bone in the lower part of the wound had been observed. I found that the appearance and general condition of the patient had very greatly improved. She had gained both in strength and weight and walked about all over the house without fatigue. She said, however, that for the last two or three nights she had been kept awake with headache which extended from the wound to the temple and occiput and that there were flashes of light and obscuration of vision. The wound had healed except for a narrow groove of granulations immediately behind the auricle. In the lower part it was covered by thin, newly formed skin; a whitish point presented itself. Upon taking hold of this with a pair of forceps, a sequestrum shaped somewhat like the letter U was easily removed, the longest branch being about 7 or 8 mm. long. Two minute spiculæ of detached bone were also removed from the midst of the granulations. The pulse and temperature were normal. There was still obstinate constipation which was only relieved by daily doses of a saline cathartic.

An examination of the eye with the ophthalmoscope showed an almost complete restoration of the optic discs to their normal appearance. There was only slight haziness of the disc margin and rather small arteries. She could readily count fingers across both communicating apartments, a distance of about twenty feet, and read easily the finest newspaper print. In the absence of any rise of temperature or aggravation of the condition of the fundus oculi, I did not consider these symptoms of any great moment and the patient may fairly be said to be convalescent.

Remarks.—This is the second case of pyemia which has occurred in my practice following mastoiditis, both of which recovered. The other one, which has never been published, was observed in April, 1892, in a young man of twenty-one years, suffering from otitis media purulenta after scarlet fever. There were swelling and tenderness of the mastoid; infection had occurred when I saw him, with high temperature and chill. A mastoid operation was made and severe pyemia ensued, involving many joints. There was septic pneumonia and choked discs and the characteristic temperature with alternate sweatings, and yet, after several months, the patient recovered. Whether or not there was thrombosis of the sinus is not stated in my record of the case.

Dr. J. B. Emerson reports "A Case of Pyemia Following Acute Suppurative Otitis: Recovery" (Transactions of the American Otological Society, 1892, p. 221), in which no operation on the mastoid or sinus was performed. There was septic pneumonia. The treatment extended over a period of four months. A number of abscesses

formed which were opened, no drugs being used except for the pain. The cause of the pyemia is not given, but, as in my own case, was probably due to sinus thrombosis of which much less was known at that time.

It is worth while recalling the fact that my patient, while suffering from the ear disease took care of a sister who died of puerperal septicemia, and to raise the question whether this exposure had anything to do with the severity of her attack. She was unquestionably septic when first seen and the examination of the pus showed streptococcus infection. Whether the pus absorption antedated the thrombosis is another point of great interest; that it did not exist at the first examination seems evident enough, although there was a necrosis of the sinus walls, in removing which the sinus was exposed and opened, but the fact that there was a very large hemorrhage at that time showed there was no clot. The symptoms of infection after the first operation which showed infection were tonsillitis, arthritis of the finger joint, chill and choked discs. It is most probable that the sequence of events was as follows: The sinus was infected at the time of the first operation. For the first three days thereafter improvement took place; then the sinus clot formed, with the subsequent appearance of the symptoms so characteristic of sinus thrombosis.

Dr. Frederick Whiting, in "A Contribution to the Symptomatology and Treatment of Pyemic Sinus Thrombosis, Based Upon Three Successfully Operated Cases" (Archives of Otology, Vol. 28, No. 1, 1898), says: "In the event of failure to re-establish the circulation from below the jugular bulb, whether you have removed a purulent disintegrated clot or not, it is your imperative duty to your patient to tie the internal jugular forthwith, as you otherwise leave wide open the main avenue to almost certain pulmonary metastases." And again, "Just at this point the writer desires to enter a vigorous protest against a procedure which has been occasionally witnessed upon the operating-table, and himself participated in, when an attempt is made to force the return circulation from below upward through the obstructed bulb by forcible manual pressure upon the muscles of the neck. I believe that all attempts at re-establishing the circulation by making pressure from below upward upon the muscles of the neck, in the hope of dislodging the clot, cannot be too severely condemned. It is a procedure in my opinion eminently calculated to favor the dissemination of obstructing infective material either directly through the jugular or collaterally through the tributary veins." I have quoted from the author verbatim, because this method, as I said in reporting my case, is the very one I resorted to, notwithstanding it had been strongly condemned by so excellent authority, and I venture to say that in the case before me it was fully justified and indeed the only thing to do. It was obvious to all who were present that the patient could not survive any further protracted operative interference, and to have left the obstructive clot in the vein would have greatly increased the hazard of the patient's recovery, while the maneuver was successful in re-establishing the return current through the jugular, and, although septic pneumonia did take place, the patient recovered nevertheless, and I contend that she was placed in a better condition for recovery by the fact that the return circulation was established. Without, therefore, saying that the procedure is always to be recommended, I am prepared to defend its adoption under similar conditions and to affirm that every rule may find exceptions and that no arbitrary one is applicable in all cases.

Another point of great interest to me was the somewhat difficult matter of determining whether the first symptoms of pus absorption were really due to sinus thrombosis. The tonsillitis was the very first symptom to cause pain and rise of temperature; then came the involvement of the finger-joint, which was so slight and the swelling, redness and pain so closely resembled gout or rheumatism and the co-existence of the tonsillitis made it more difficult to differentiate between this and arthritis due to pyemia. This, however, was made easier when the temperature rose and the other symptoms, especially the choked discs, made their appearance. Septic pneumonia was the gravest symptom presented by the patient. Neither of the joint involvements went on to the formation of pus, and, although the peripheral abscesses were exhausting to the patient, they were nevertheless accessible to surgical treatment and reach. I may mention that besides being freely opened they were kept drained by gauze and thoroughly cleansed by antiseptic injections.

While speaking of local treatment, I wish to call attention to the use of antiphlogistin, which was used as a dressing for the pneumonia, swollen joints, and indurations preceding the local metastases. In all of these it was most beneficial in allaying pain and especially so in the pain in the side caused by the pneumonia, the patient herself speaking loudly in praise of the remedy. Another method for the relief of the pain in the swollen ankle-joint of which I wish to speak is the suspension of the foot and leg, so as to take the weight off the joint and heel. This was done for several hours daily during the height of the joint involvement.

The neuroretinitis at the last examination had subsided and the patient saw well, although no accurate examination of the acuteness of the vision was made. It may, therefore, go on record as one of recovery after intra-ocular involvement, in which cases, according to Kipp, the percentage of recoveries is about 50 per cent.

In conclusion it must be instructive to recall to mind the recovery of such cases whenever they occur for the encouragement of those who may feel that such conditions as were present in this case, both before and after the operations, were most discouraging, and the prognosis apparently hopeless.

THE SURGICAL TREATMENT OF ACQUIRED INCONTINENCE OF URINE IN WOMEN.*

BY CHARLES GREENE CUMSTON, M.D.,
OF BOSTON, MASS.

THERE is nothing perhaps more disagreeable nor heartrending than a case of incontinence of urine in women and the surgeon will never have a more grateful patient than the one he cures of this affliction. Every practitioner comes in contact sooner or later with these unhappy patients seeking relief of their infirmity, and it is on account of the importance of the subject, rather than the relative infrequency of these cases, that I desire to call your attention to the subject of their treatment.

This paper will only discuss the surgical treatment of what may be termed acquired incontinence of urine, and will deal in no way with the so-called infantile variety of the affection. Incontinence may follow traumatism of the neck of the bladder or urethra; we often meet elderly females, especially those who have given birth to several children, afflicted with incontinence of urine. In the latter case a traumatism may be incriminated as the etiological factor, but it is less evident, because the affection appears to become spontaneously established little by little. We will first consider incontinence of urine having a traumatic urethral origin, then spontaneous incontinence and, lastly, a third variety which appears to have a close relationship with uterine displacements or the presence of vaginal cicatrices.

Considering first incontinence having a traumatic origin involving the urethra, it may be said that the injury may have acted on the internal aspect of the urethra, a condition which is particularly met with in various cases of dilatation of the canal. This dilatation of the urethra may be a pathological one, produced by the passage of a calculus or a neoplasm.

The female urethra presents very little resistance to dilatation, especially when this takes place progressively from within outward, and it is readily conceived how a foreign body arising within the bladder may enter into the urethral canal under the influence of pressure of the bladder walls. If by chance this foreign body is of large size, it takes some little time to be expelled and if its surface is rough it naturally produces a traumatism of the inner surface of the urethra which may result in quite serious lesions. A tumor of the bladder provided with a long pedicle may enter into the urethra and if it requires some little time to dilate the canal it may produce an incontinence which will remain after the neoplasm has been removed. In the same way very large calculi may enter the urethra and there remain for quite a long period before being expelled. Under these conditions, the walls of the urethra will become injured at different points and according to the seat of the lesion the resulting incontinence may or may not persist. Should the calculus become arrested below the sphincter of the bladder it may either perforate the urethrovaginal septum or it may dilate the urethral walls at their lower aspect. If, on the other hand, the calculus should stop at the level of the vesical sphincter it will produce serious lesions which will persist for a long time and be the cause of a total incontinence, especially when the surface of the foreign body is rough or irregular.

Surgical dilatation of the urethra must also be considered in relation to pathological dilatation. It is often undertaken for the removal of foreign bodies from the bladder or for the purpose of diagnosis in genito-urinary or gynecological affections and this practice was very much in vogue for a number of years, but at the present time it is far less often resorted to on account of incontinence of urine which often follows it. Many cases of incontinence following surgical dilatation of the urethra could be mentioned but the reports given us by Estrabaud, Desnos, Emmet and others, are quite sufficient to show that it not infrequently results from this cause.

It is quite difficult to say what the exact lesions are which produce incontinence after dilatation of the urethra. Unquestionably, if there should be a more or less complete destruction of a part of the urethra, if necrobiosis should have taken place, it may be admitted that a portion of the muscular structures of the canal have been injured. But when no laceration can be found the surgeon can acquire little idea as to the nature of the productive cause. I would point out, however, that Emmet had the opportunity of performing a necropsy in a case of incontinence occurring after rapid dilatation of the urethra in which he found the muscular tunic of the canal forming a hernia through the lacerated mucosa. In another case, he found de visu the presence of a cicatrix involving several of the folds which border on the neck of the bladder. In both these cases, it is evident that lesions of the sphincter were present and it might be admitted that when lesions are less marked than in these two cases a submucous laceration of the sphincter of the urethra may have taken place, resulting in a cicatricial sclerosis.

A traumatism may act on the vaginal wall of the urethra and we consequently must consider incontinence following labor and incontinence resulting from the removal of vesical neoplasms or calculi by the urethra.

Incontinence following labor may arise under several conditions. In the first place, it is easy to conceive how the urethra or the neck of the bladder may be more or less violently injured by the forceps or manual operations during a difficult labor. It is needless for me to consider this aspect of the case and I will immediately pass to the study of the mechanism of incontinence of urine following normal

* Read by invitation before the Stafford District Medical Society, Dover, N. H., Oct. 14, 1903.

labors. At the time of labor, the bladder may be empty and this is usually the case when the act takes place rapidly because the head of the child presses the walls of the bladder against the pubis. It is more especially the lower half of the bladder which is pressed upon by the fetal head and naturally it undergoes more or less pressure from this cause; the muscular layer of the bladder will afterward contract with less ease from which various symptoms arise according to the point of the viscus which has received the contusion. Retention of urine will result if the wall of the bladder itself is the seat of the contusion while an incontinence, usually only temporary, will take place if the pressure has been more marked in the region of the neck of the bladder. When labor has been protracted, when the head of the child has remained engaged for some time in the true pelvis, the bladder becomes filled with urine, rising above the pubis and then it is no longer the bladder that is compressed but the urethra and this pressure on the canal is all the more marked the higher it is drawn up by the ascension of the bladder. In all these cases, however, it is quite difficult to comprehend clearly the disorders produced at the vesical neck or the urethral walls.

In one case reported by Milne-Murray, this authority believes that pressure may produce a necrobiosis which will lead to the destruction of a certain amount of the muscular structures of the sphincter. Other authorities uphold that the walls of the urethra simply lose their elasticity and power of contraction and they deny the existence of laceration of the muscular structures. For convenience, however, it may be said that the lesions produced in labor may be classified under two heads, namely, those in which contusion has taken place resulting in a slight paralysis which gives rise to a temporary incontinence, and secondly, deep interstitial ruptures producing a permanent incontinence. I would only mention in passing, that numerous cases of incontinence of urine have been reported following the operation of symphyseotomy, some of which have been only temporary while others have been permanent.

As to incontinence of urine following vesical operations performed after dilatation of the urethra, it may be said that on account of the relative frequency of this complication following this modus operandi, the urethral route is now less frequently resorted to than formerly.

The mechanism is easily understood. An incision of the sphincter is necessary and although an immediate suture may oftentimes result in restoring the normal action of the muscle, this is not always the case and frequently after the wound is closed a cicatricial transformation arises which greatly diminishes, or even prevents, the proper functions of the cut muscle. The practical conclusion is that if the surgeon is desirous of removing a neoplasm or a vesical calculus by a vesicovaginal incision, he should take particular pains to carry the incision at a point low enough to avoid involving the sphincter. But I would add that such brilliant results are now obtained by the suprapubic operation that no man well versed in general surgical technic would probably resort to this tinkering at the present time.

Some women progressively develop an incontinence of urine when no former history of traumatism of a surgical or obstetrical nature can be elicited. It is especially in elderly women that this unfortunate affliction arises, occasionally at about the time of menopause. The urine will escape in large amount upon the slightest provocation. However, a total incontinence is rarely present and in these cases we are usually dealing with a weakened sphincter which has lost its resistence to such a point that it cannot overcome the vesical pressure. These cases are not of uncommon occurrence and are extremely annoying.

Whether or not the explanation may be found in a loss of tonicity of the sphincter appearing at a time when a general relaxation of the perineal muscles takes place or whether there is simply a decrease or an absence of the voluntary muscle fibers of the sphincter, which sometimes are replaced by a hypertrophy of the involuntary muscle fibers, is as yet an unsettled question, because, so far as I am aware, no histological examination relative to this point has as yet been undertaken.

In certain cases of uterine displacements, especially in prolapsus uteri, difficulties in micturition arise and I have frequently noted that incontinence of urine is a very early functional symptom of this condition. Without any question this incontinence is related to a former labor in cases where the prolapsus results from former obstetrical mishaps. In these cases those lesions already described might naturally be invoked as the cause of incontinence in the cases that I am just now referring to, but it should be pointed out that incontinence is quite as frequently met with in instances of prolapsus which slowly develop, accompanied by cystocele and rectocele, added to which there is a general weakness of all the muscles forming the pelvic floor.

In these cases a relaxation of the neck of the bladder and urethral structures must be incriminated, as well as the traction exercised on the urethra by the prolapsed anterior vaginal wall. This same action is also met with in women who present an ascension of the cervix uteri when the uterus is the seat of a fibroid tumor and in these cases we occasionally find the urethra pulled upward while the meatus is hidden deeply under the pubis; the latter is gaping and under these conditions it is not at all surprising to find that the patient suffers from incontinence.

The importance of a congenital development of fibrous tissue uniting the bladder and uterus very intimately, with marked anteversion of the uterus, setting up persistent incontinence, must never be lost sight of. The mechanism is practically the same as in the case of incontinence from upward traction of a fibroid uterus, but in the former

the subjects of the affliction are usually young, unmarried girls or women, who seek relief for this terrible infirmity and the remarkable results which may be obtained by the operation which I shall describe later on, will always be a blessing to these unfortunates. In other cases incontinence in young women and girls may be the result of the presence of fibrous bands which bind the neck of the bladder or the urethra to the vagina.

Under this same heading we should also include cases of incontinence of urine following the operation for the closure of vesicovaginal fistula, because, although in some cases it may be believed that the fibers of the vesicourethral sphincter have disappeared, in others it is distinctly proven that the cicatrix resulting from the obliteration of the fistula, drags on the urethra, holding it gaping, thus producing an incontinence in the same manner as other lesions already mentioned. One should also recollect that, after the radical operation for an old vesicovaginal fistula, there are other hindrances to the normal retention of urine within the bladder. The latter organ has lost its extensibility, is irritable and intolerant and in order to resist the desire to void urine the sphincter should be more powerful than under normal conditions, but it is exactly the contrary which takes place and from which results incontinence. This is only half the truth, however, because it is well known that after the closure of a suprapubic fistula the urethra preserves all its functions, which would go to show that, after the cure of a vesicovaginal fistula, the incontinence is largely due to the traction exerted on the urethra.

Considering now the surgical treatment for the relief of incontinence of urine, it will simplify matters if we classify the cases which resemble each other anatomically, disregarding completely the cause which has produced the lesion. In some cases the urethral canal is present in its entire length and after a superficial examination it would be quite impossible to say why there was incontinence, but in other cases there is a more or less complete destruction of the urethrovaginal septum which may even involve the neck of the bladder. The treatment will consequently vary according to whether the urethral canal is present or not and we will study first the manner of treatment when an abnormal traction on the urethra from a neighboring part exists; secondly, when the urethral canal exists, but with a more or less complete destruction of the sphincters; thirdly, when there is destruction of the canal with an intact vesical sphincter; and lastly, when there is destruction of the canal with loss of the sphincters.

In cases where an abnormal traction on the urethra is present the treatment will vary because this traction may be exercised by a uterus or a prolapsed vagina, or, on the other hand, it may be due to a congenital displacement of the uterus or a cicatrix situated on the anterior vaginal wall. It is at once evident to all that, in cases of prolapsus uteri, an appropriate treatment should be in the first place directed toward the latter condition without taking into consideration the bladder symptoms. It is not my intention to enter into a discussion of the cure of prolapsus of the female genital organs but I would say that when a properly conducted radical cure of this condition has remained without effect on the incontinence of urine, it is evident that there still exist lesions of the urethra or neck of the bladder which, however, do not enter into the class that I am now considering and to which I will revert further on.

If incontinence of urine is present along with a congenital displacement of the uterus, in antiflexion, for example, we are then dealing with a traction exercised upward and backward on the urethral orifice by the cervix. There will be found abnormal adhesions existing between the bladder and uterus and the rational treatment would naturally be to free the organs of these adhesions. This can be successfully accomplished by making a transverse incision over the anterior aspect of the cervix and then peeling the bladder off of the organ exactly as is done in vaginal hysterectomy. After the bladder has been thoroughly freed from the anterior aspect of the cervix, the wound is simply packed with gauze and allowed to granulate, so that the abnormal relationship between the organs cannot be re-established. This operation has given me two of the most beautiful surgical successes that it has been my lot to meet with. In both cases the patients were young unmarried girls who had suffered from incontinence of urine for a number of years. In each case every conceivable treatment had been tried without any relief and the cure was immediately obtained by the operation here described, showing that this etiological factor must never be overlooked.

When an incontinence of urine is observed after the operation for vesicovaginal fistula, an endeavor should be made to find the true cause of the former. By thorough cystoscopic examination of the cavity of the bladder, by ascertaining the capacity of the organ by passive distention, we can readily conclude whether or not we have a pseudo-incontinence due to a cystitis. By the use of the olive bougie the resistance of the vesical sphincter can be ascertained. Should these examinations remain negative, the surgeon will probably be right in concluding that bands of cicatricial tissue are present which drag upon the urethra, in which case the proper treatment would naturally be the prudent division of these bands and, if necessary, the separation of the bladder from the uterus, employing the same technic already recommended will probably be of great value.

In all cases, when present, fibrous or cicatricial bands starting from the urethra and extending in various directions, by the traction they produce on the canal, will cause incontinence, the radical and complete cure of which may be obtained by careful division of these bands as has been done with brilliant results by my friend, Dr. Gilliam, of Columbus, Ohio.

When the urethral canal persists with a more

or less complete destruction of the sphincters, the first thing to do is to examine the condition of the latter as well as their resisting force, and in order to ascertain this point the use of an olive bougie must be resorted to. If in passing the instrument, no resistance is felt, one may conclude that there is a considerable loss of muscle tonicity. In order to bring it back, electricity applied locally, combined with massage will sometimes restore the functions of the sphincter, if persisted in for a sufficiently long period. When, however, all hope of restoring the functions of the sphincter is lost, recourse to operative procedures is indicated. These may either act directly on the vaginal wall and on the urethra, or the operation may simply be applied to the latter alone.

In the first class of operations, all are similar to anterior colporrhaphy. For example, Engstroem removes a triangular flap of mucous membrane, its apex corresponding to the neck of the bladder while other operators have thought it better to remove a corresponding part of the urethral wall along with a bit of the vagina. Schultze excises an elliptical flap three centimeters long and one centimeter broad at its widest point while Winckel forms a wedge-shaped flap whose narrowest part corresponds to the mucosa of the urethra. Frank removes two flaps, the first of which is an anteroposterior cuneiform one, comprising the entire vesicovaginal septum, while the second is made transversely at the level of the posterior urethral orifice, that should only include the vaginal mucosa.

Among the second class of procedures may be mentioned the transversal and longitudinal folding of the urethral mucosa, torsion of the urethra and traction upon it with elevation of the meatus. Transversal folding has been done by Desnos as follows: a longitudinal vaginal incision is made over the urethra, the canal is then dissected out and a large catgut ligature is passed around it. After having introduced a No. 15 catheter the ligature is tied and a kind of circular valve is thus formed.

Longitudinal folding of the urethral mucosa may be either done on the anterior wall of the canal or on its lower wall. In the first method the urethra is dissected on its upper aspect underneath the pubis and then a longitudinal suture is inserted on its external wall so that a fold is formed which projects into the lumen of the canal, extending up to the meatus. In the second technic, the urethrovaginal septum is incised longitudinally and two lateral flaps are formed and after having brought them together in the median line they are united at their base. The circumference of the urethra is thus decreased and a median inferior urethral crest is formed.

Torsion of the urethra was first employed by Gersuny with the aim of forming a series of obliquely spiral folds, dovetailing each other. The meatus having been circumscribed by a circular incision, the urethra is dissected backward for about two centimeters. A suture is then placed opposite the upper pole of the canal which is then twisted on itself until an angle of 180° is formed, then the parts are sutured in this position after the introduction of a fine bougie has assured the operator that the lumen of the canal is not completely obstructed.

Instead of decreasing the caliber of the urethra by the formation of projections within its lumen, endeavor has been made to retain the walls in close permanent apposition by bending the urethra under the lower aspect of the pubis.

To accomplish this the urethra must be elongated and the meatus should be united at a point much higher than its normal situation. At the same time it is well to decrease the caliber of the meatus which may be transformed into a transversal opening. This was first done by Pawlick and later on Duret improved the procedure successfully. It is not to be wondered at that in order to obtain a more perfect result torsion and traction have been combined. It is not necessary to describe the technic in this instance since it can easily be guessed at from the description already given of the other two procedures.

To sum up, it may be said that when there is destruction of the sphincter with persistence of the urethral canal, the operation may be simply a colporrhaphy, alone or combined with an elevation of the meatus. I would point out that it is better not to open the urethra because the formation of fistulæ is to be feared and should the urethral walls be thin torsion should not be undertaken.

When incontinence of urine appears to be due to a more or less complete destruction of the urethral canal, the rational indication is to repair the urethra and replace the organs in the situation and relationship that they normally occupy. When bits of mucosa or strips of tissue susceptible of being utilized are still present, they should be used in reconstructing the canal. When, on the contrary, and this is the usual case, no bits remain or when these are either too small or too thin, an autoplastic procedure must be employed for making the new urethral canal. If the loss of substance is situated far forward, the labia minora may be utilized, but if the injury is further back, flaps may be made from the vesicovaginal septum or simply from the vagina. If the entire urethra is destroyed, flaps must be obtained from both the vulva and vagina.

All these various procedures have given good results but in order to be successful a large amount of patience is required by both patient and surgeon. Often the operation has a most successful immediate issue but the ultimate result is far from ideal. Either the sutures have become lax or small secondary fistulæ are formed at the points of sutures. In order to obtain a cure very large flaps should be cut, so that the new canal will have very thick walls which, when sutured, will not be pulled upon by the surrounding parts. It is more than useless to try to accomplish everything in a single operation and the patient must submit to several interventions. In

each one the least possible dissection should be made and if the surgeon will make up his mind as to the absolute necessity of small, successive and uncomplicated interventions, a complete restoration of the destroyed urethra will be made, even if the incontinence of urine is not completely controlled.

Local treatment of the bladder and progressive distention of the viscus, prolonged electrization of the sphincter, are necessary in order to bring about a complete cure.

Two procedures of entirely different nature may be resorted to when both the urethral canal and vesical sphincter are destroyed. Starting on the principle that after restoration of the urethra has been accomplished, the absence of the vesical sphincter may keep up the incontinence of urine, certain operators have discarded autoplastic operations and have simply made an artificial meatus which is easier to control than the original fistula. Naturally, suprapubic cystostomy is at the present time the operation of choice, but after this operation continence is infrequent, so that I can hardly commend this method. It is well known that suprapubic cystostomy performed on prostatics has, in some cases, resulted in absolute continence, but it is safe to say that the contrary is usually the case.

When destruction of the urethra and neck of the bladder co-exists, I believe it should be the duty of the surgeon to direct all his efforts towards restoring the urethra and if a canal sufficiently long be made, if its caliber and the thickness of its walls are sufficient, the incontinence will be much diminished and a considerable improvement will be obtained. If, however, the affliction continues, palliative methods must be resorted to, such as urinals and various forms of pads which compress the canal. All these means are naturally very unsatisfactory but when all surgical methods have been tried, one must be content with any method which may relieve the infirmity.

SOME SUBJECTIVE HINTS OF THE MORPHINE HABIT.

BY WILLIAM LEE HOWARD, M.D.,
OF BALTIMORE, MD.

WHILE both objective and subjective symptoms are clear and incised enough in the morphine victim to make positive a diagnosis, the few subjective signs in the very early stages of the use of the insidious drug are not always to be detected by the practitioner, and seldom by the user's most intimate friends or relations. The husband, the father or mother may have one loved living in the family circle who is approaching that period when secrecy becomes impossible and cure questionable, yet whose increasing dependence upon morphine is never suspected.

An appearance of slight ill health, irritable and unreasonable conduct at times, intestinal disturbances, or loss of appetite with anemic indications, will cause the victim's friends to have her consult a physician. Now is the time for all the latter's intuition and mental notes of experience to be active. If the consultant has had his wits sharpened by the manifold subterfuges and masked confidences of neuropaths, he will hesitate before making any diagnosis in these alleged cases of a "general run down of the system." In dealing with the beginner in the use of the drug he must recognize that the neuropath is yet only in the grasp of one of the tentacles of this octopus, and now is the time to tear away forever this sucker of morals whose fascinating embraces breathe wily stratagems and golden promises.

If, after carefully considering the physical symptoms as told by the patient, and especially the details of life and conduct as seen by her intimate friends and family, and by close questioning and examination, you find no rational cause for the general systemic disturbances, you are justified in suspecting the use of morphine, but that suspicion must lie so hidden, that not by sign, look or word could the acute watcher and observer—for such she will be—gain a hint to your thoughts. This attitude is necessary to accomplish your ends and to render all justice to the patient should your suspicions prove erroneous.

The patient should be treated for the distressed feeling she complains of, letting her understand that this treatment must continue for several weeks. This understanding is necessary if you wish to get at the truth.

Laying considerable emphasis upon the importance of seeing her at a certain time, make an appointment the next day for an early hour. If it is in the afternoon that you have had your first consultation—and such will probably be the case—watch carefully the conditions existing in your patient—the restless attitude, the inclination to talk upon subjects foreign to her symptoms, the furtive glances and the eyes generally. Are the latter bright, and do they harmonize with her words and actions? Is she voluble, sanguine, and apt to consider her distress of minor importance, and say she feels "much better to-day"? An appointment for the next day she readily promises to keep to the minute, and if you have well acted your part the patient leaves your office feeling confident that she has "fooled another doctor." On the next day the appointed hour passes, and noon arrives with the patient hurrying into your office with her cheeks flushed, and she at once pours out voluble excuses for her tardiness. The excuses must be accepted with every appearance of belief. Again notice the general attitude of the patient. It may or may not vary in degree from that noticed the day before, but the treatment must be the same.

Now comes in the astuteness of the consultant: he must find out without causing suspicion what her conditions are in the mornings. Does she eat a substantial breakfast? Is her appetite wanting; or is it capricious? Is she irritable and dilatory about making her appearance, drowsy and diffi-

cult to arouse, but when ready to leave for her engagements, voluble and sprightly? All, all these apparently minor facts must be well considered.

The third day she is again late, later than she was in keeping the first engagement, but remarks that she had no idea she was so much behind the appointed time. Now is the time for clever dissembling on the part of the physician. Let him appear at her house the next morning at a reasonable hour, with the excuse that he could not keep the office hour, and, not wishing to have the day pass without seeing her, he called. He will probably be told that she is not down. "Will he wait?" Yes, he will wait, and should he be detained a half hour and then see his patient appear with every evidence of a hasty and careless toilet, moist skin, pale face and vapid, filmy eyes, he may satisfy himself that he is on the right track. He will not be able to keep his patient long, for the small "shot" she has taken is not sufficient to enable her to control a feeling of fear and weakness, and she will in a nervous and irritable manner ask him to excuse her. After this occasion the observer must see her under different circumstances; at night, at a period when she is self-controlled—or rather drug controlled—mentally bright, and on her guard. When this condition is contrasted with those seen in the mornings, the experienced observer cannot fail to recognize the great psychic change. Let him now watch for verbal contradictions, exaggerated statements, and, sometimes, erotic tendencies, for now the evening physiologic rhythm is controlled by the influence of the drug. Make another engagement for an early hour, and when it is not kept you will realize how impossible it is for these cases to ever recognize the value of time or promise.

Objections, naturally, will be made when one advises using such factors as late rising in the morning, drowsy appearances or unfinished toilets, as diagnostic factors. Among our mental workers and devotees to society such conditions are almost universal, therefore what value can be placed upon such conditions? No value at all, taken alone, but taken as gradual changes from former habits, accompanied by decided psychic and moral evolutions, they have decided value.

To place and analyze such changes; to eliminate physiological causes, psychic shock, irritating environment, etc., is no easy task, yet a necessary one in making a diagnosis. Upon the statements of the intimates of the patient much depends, yet one must be always on guard as to the motives of such friends. A history of uncontrolled impulses in childhood is an important matter, as it shows a neurotic basis. If all accounts agree that the morale of the patient is gradually changing, that where she was formerly truthful she is now careless of her statements, that she makes engagements and promises which are not kept, that her sense of relation and duty to others has become dull and her ego exaggerated, we can come to the conclusion that we are dealing with a user of morphine.

Up to this point we have been given a clue as to the cause of the subjective symptoms complained of by the patient and family. The further facts which the physician will want before hinting his suspicions to the family, are not easily gotten. He will want to know where she purchases her drug, and how she uses it. Taken alone, the appearance of the eyes has no value. So expert have these morphine victims become in the use of atropine that the condition of the pupils tells little. You may ask for the urine and expertly examine it for the crystals, only to find later that you have examined the maid's urine; as once happened in a case of the writer.

I have in the above remarks only lightly touched upon some of the problems entering into the early diagnosis of the morphine habit. It seems almost surplusage to make any remarks concerning the absolute unreliability of statements made by the patient herself. One of the first effects of morphine is to destroy the responsibility of the ego; to submerge the individual's recognition of her place in the world, to make her purblind to the difference between *meum* and *teum*, or to allow her to ever get away from the powerful influence which constantly focuses the mental energies on the self.

THE HEMORRHAGIC DISEASES AND THEIR ALLIES IN THE LIGHT OF MODERN PATHOLOGY.*

BY F. L. WACHENHEIM, M.D.,

OF NEW YORK;

ATTENDING PHYSICIAN CHILDREN'S DEPARTMENT, MT. SINAI HOSPITAL DISPENSARY, NEW YORK.

The customary inclusion of the hemorrhagic diseases among the blood diseases is most unsatisfactory, for, in so broad a sense, these may be held to include nearly all the infections, intoxications, and errors of metabolism, approximately one-half of the field of internal medicine. Many recent authors, like Litten,[1] group these affections into a class by themselves, on the common basis of the symptom of hemorrhage. We shall see that this classification is far from meeting modern scientific requirements; these diseases do not even agree in the cardinal symptom, as will be presently shown; in other respects some of them differ so widely and profoundly, as to present scarcely any points of contact whatever.

Our study will be best begun with a brief discussion of the nature and causation of spontaneous hemorrhage. Cohnheim[2] and Arnold[3] showed that it is caused by a yielding of the intercellular cement of the vascular wall resulting from impaired nutrition, in many, but not all cases, favored by a local rise of blood pressure, which is regularly due to a thrombosis. The question naturally arises, whether the malnutrition or the thrombosis is the primary factor,

* Read before the Pediatric Section, New York Academy of Medicine, Oct. 8, 1903.

and here the authorities disagree; Von Kogerer[4] declares that the thrombosis is secondary to the vascular degeneration, whereas Silbermann[5] claims that the impairment of the vessel wall is the result of the thrombosis and the consequent rise in the intravascular tension. As we go on to consider the various hemorrhagic diseases seriatim, we shall find support for both views, neither seeming to obtain universally. Aside from the stated question, however, one fact stands out clearly; degeneration of the vascular endothelium must follow either a deficient food supply or the presence of a poison in the blood, and experience has shown that these two factors always coexist. It will, therefore, be necessary to proceed at once to the consideration of poisons in general and blood poisons in particular.

Poisons, in the popular sense of the word, may be classified along two lines. According to their origin, we distinguish between poisons derived solely from the body tissues, and such as are either directly introduced or are secondary to the introduction of a foreign substance; thus we have endogenic and exogenic intoxications. According to their biochemistry, we observe two very different modes of action on protoplasm, requiring a somewhat extended description.

It is easy enough to understand the effect of an ordinary chemical poison. If corrosive sublimate, for instance, be brought into contact with living cells, it will form a firm combination with their protoplasm, rendering it permanently incapable of performing its physiological functions, in fact, divesting it of the properties regarded as specific to protoplasm. The process of cell destruction continues until all the molecules of the poison have entered into combination, at which point it ceases; but, if the organism as a whole survive, and a fresh quantum of the same poison be introduced, a new series of cells will be affected exactly as those before, the first intoxication having conferred no immunity to subsequent administration of the same noxious agent. Poisons of this class are notable for destroying protoplasm wherever encountered.

A subdivision of the chemical poisons consists of those substances which form only a loose combination with protoplasm, a sort of external attachment, easily broken up or neutralized. These poisons are selective, choosing some animal cells and ignoring others, not permanently destroying the protoplasm, but causing merely irritation or inhibition. In time, in certain cases, the cells may become habituated to a substance of this class, and refuse to be affected by it; but we shall see that this loss of chemical affinity bears no resemblance to an acquired immunity in the true sense, a radically different condition. To the above subdivision belong the alkaloids and their allies, the ptomains.

The poisons of the second class, called toxins, differ widely from all the preceding. In the first place, they are proteids, therefore not entirely foreign bodies, but akin to the cell foods; like them, they are absorbed by the protoplasm and give rise to cell metabolism, differing from the true foods only in that they damage the cells. Ehrlich's[6] ingenious and now generally accepted theory of this process is as follows: In the protoplasmic molecule there is a "side chain" of proteidophile atom groups called "receptors"; when a toxin molecule becomes attached to such a receptor, new receptors are segregated from the protoplasm; as toxin absorption proceeds, the new receptors are formed in an increasing ratio, and, when their number becomes excessive, are finally set free, ready to attach themselves to further toxin molecules before these can reach the cell receptors. As soon as the free receptors are sufficiently abundant fully to protect the cells, we obviously have the whole tissue rendered immune to that particular toxin; these free receptors are then the "immune bodies," in popular language the "antitoxin." It is this production of immunity which constitutes the essential difference between the respective actions of ordinary poisons and toxins.

We may now transfer the above phenomena to the blood. As to the chemical blood poisons, we must consider separately a group having a specific affinity for the red blood cells, namely, the hemoglobin poisons. Potassium chlorate is an excellent example of this series; it causes a firm oxidation of the hemoglobin into methemoglobin, but the discoplasm of the erythrocyte as a whole does not become disintegrated until the process has advanced so far as to impair its nutrition; only then is the methemoglobin discharged into the blood plasma. The same effect is produced by the entire nitro-group (the anilin derivatives, nitrites, etc.), and analogous changes follow poisoning with sulfureted hydrogen, cyanogen, carbon monoxid, sulfonal and so on. In all these cases, in the early stages at least, before the cells break down, any spontaneous bleeding must be caused by simple malnutrition of the endothelium, conditions favorable to thrombosis not being present; we have seen that these poisons attack the hemoglobin exclusively, thrombosis requires agglutination of the blood cells, and this can occur only when the discoplasm is attacked as a whole.

Apart from the hemoglobin poisons, the chemical blood poisons present no especially distinctive features. When the blood cells as a whole are attacked, agglutination takes place, we have then thrombosis with its increased local blood pressure, extravasation can readily take place. As to the effects of the alkaloids and ptomains, as suggested, some, like quinine, seem to affect the blood alone; others, like atropine, attack the blood as well as other tissues; a third group, like morphine, have little or no action on the blood cells.

Finally, it will be best to speak of all the chemical forms of blood cell destruction as "blood dissolution," for I think that the term "hemolysis" should be reserved for the process caused by the toxins. Thus, much of the existing confusion in nomenclature can easily be obviated.

Recent investigation has shown that the action of the toxins on the blood cells is somewhat complicated. Ehrlich and Morgenroth[7] showed that the hemolysis caused by the injection into the blood of a foreign serum depends upon two components. The former, a stable "immune body," unites with the cell receptors of the host, causing agglutination, but no further injury. It is the latter, an unstable substance, the "complementary body," which actually destroys the cells, but would be incapable of so doing, were not the receptors first fixed by the immune body as "intermediary body" or "amboceptor." The amboceptor must be introduced from without, but the complementary body is not necessarily of foreign origin, and may be supplied by the serum of the organism attacked; thus, the essential step in producing hemolysis is the introduction of a toxic amboceptor, the determining factor in the process, though not, as we have seen, the actual "lysin." The relation between hemolysis and immunity thereto is plainly reduced to a matter of the respective affinities of bodies of the receptor type.

A foreign serum from a different species produces "heterolysis," one derived from another member of the same species "isolysis," less intense, as would be expected. "Autolysis" would, at first glance, appear impossible, and at one time its existence was strenuously denied; its occurrence, however, has now been demonstrated beyond question, and we shall presently have occasion to observe its great pathological significance.

Snake venom may be regarded as the type of a blood toxin; Flexner and Noguchi[8] showed that, after reduction to a mere agglutinin by destroying the complementary component with moderate heat (56° C.), its full hemolytic power is restored by adding any normal serum to supply that body afresh. I might mention, in passing, that its action on nerve cells was found to be relatively feeble, contrary to the popular belief, immunity being rapidly acquired in that tissue, while in the blood, on the other hand, the extreme intensity of the venom makes the acquisition of immunity far more difficult, large doses destroying the cells far more rapidly than new receptors can be liberated.* Among other blood toxins that have been found in the animal and vegetable kingdoms, I mention merely abrin, ricin, and, above all, the bacterial products, such as tetanolysin, staphylotoxin. The action of all these substances has proved so far identical, except in degree, as to give rise to the opinion, also sustained by experiment, that there is but one kind of lysin complement; the newest researches, however, seem to prove that such is not the case (Ehrlich and Marshall[9]).

The Autogenic Hemorrhagic Diseases.—In considering the autogenic hemorrhagic diseases, we may begin by taking up the subject of autolysis at the point where we temporarily dropped it. Within certain limits, in view of the constant destruction of blood cells going on in the circulation, it is probable that a process that must be called autolysis is normal, and becomes pathological only when unduly accelerated. Such acceleration may be caused by the resorption of amboceptors from within the body, the most available source being an internal hemorrhage. As a matter of fact, Grawitz[10] did observe degeneration of the blood cells under such circumstances, but the rapid formation of immune bodies would obviate extensive destruction by autolysis from this cause. In a severe or continuous autolysis it will be necessary to look for some form of internal secretion of amboceptors as the result of a perverted metabolism, or for the retention of amboceptors that should be excreted. Let us assume, that large quantities of such amboceptors, *i.e.*, auto-agglutinins, are being continuously resorbed into the blood: in this event there will be a constant liberation of anti-auto-agglutinins, with a result beyond the mere inhibition of hemolysis. For, if we refer to the familiar process of the coagulation of extravasated blood, and regard the fibrin ferment, as we must, as consisting of a zymophore complement and an auto-agglutinin, the latter mostly derived from breaking down of leucocytes in the course of extravasation; it is plain that, when the blood is already fully charged with anti-auto-agglutinins, the first step in coagulation will be interfered with, and the fibrin-forming complement cannot be activated. The blood will then continue to exude without clotting, giving us the clinical picture called Hemophilia.

Before discussing this new theory of hemophilia, we may briefly look back at the older views. Our ignorance on this subject was so profound, that we could not even say whether we were dealing with a true disease or an error in development; the hereditary and congenital features made the latter view very tempting, though nothing was really explained thereby. W. Koch[11] considered it a bacterial infection, but his view is hardly tenable; his evidence is very imperfect, and I shall show his assumption of identity with scurvy to be entirely erroneous. Resting on certain observations of Virchow,[12] Immermann[13] proposed an explanation, that has gained wide acceptance. He claimed that the essential lesion is a congenitally arrested development of the blood vessels, which are thus incapable of resisting even a moderate increase of the intravascular tension. It will suffice to point out two flaws in this theory. First, an exactly similar maldevelopment of the vessels occurs without any hemorrhagic diathesis; secondly, the failure of the blood to coagulate remains unexplained. I must not fail to emphasize the fact that the characteristic symptom of hemophilia is not spontaneous bleeding, as so often assumed but never yet demonstrated, but defective coagulation, as before stated. Blood analyses have

*Tetanotoxin is another conspicuous example, in another tissue, of a toxin so intensely destructive as to make even artificial immunization almost impossible. Similarly, immunization to the toxin of diphtheria would often fail without artificial aid, which, in turn, must be administered promptly to be effectual.

shown no want of fibrinogens, *i.e.*, agglutinins; the failure of the extravasated blood to form rouleaux is, of course, due to absence of agglutination. Alex. Schmidt[14] did cause hemophiliac blood to clot promptly by adding what he called a "zymoplasma"; in the light of modern research this "zymoplasma" undoubtedly contained foreign amboceptors, against which, naturally, an anti-*auto*-agglutinin would be powerlesss. Under the new theory, Schmidt's experiment should furnish the clue to a rational plan of treatment.

The failure to acquire immunity is the corollary to our theory of hemophilia, as the disease itself is a pathological immunization. Two difficulties present themselves for elucidation: first, the source of the original agglutinin; secondly, its constant production throughout life. As to the former question, we are in position to furnish a parallel, presently to be referred to; as to the latter, we cannot so far give a perfect analogy. Though we know of other internal secretions, producing pathological changes, that are both congenital and continuous, such as those causing cretinism and obesity, we cannot instance them without a certain reservation. Arguments based on premises so little understood are apt to involve serious fallacies. With regard to normal secretions of this type, we are not at a loss; the digestive fluids are in every way sufficient instances.

Returning to the first question, we have in obstructive icterus an auto-intoxication that presents a blood condition practically identical with hemophilia except as to permanence. Grünbaum[15] demonstrated the presence of agglutinins in the blood in jaundice, as evidenced by its action in cultures of the typhoid bacillus; such formation of agglutinins we know to require absolutely the presence of a toxin, as before stated; the bile being an internal secretion, the auto-toxinemia in icterus must be regarded as a settled fact. If the biliary obstruction and resorption continue for any space of time, an extensive production of anti-auto-agglutinins is inevitable, the resemblance of the mysterious idiopathic hemophilia to the readily comprehended icterogenic hemophilia is most striking and convincing. If Ehrlich's theory has any merit at all, the causation of hemophilia here outlined is not likely to be effectively controverted.

A few words as to the older theories of the blood changes in icterus, now practically obsolete. Rywosch[16] caused blood dissolution by the injection of large doses of the bile salts into the circulating blood; excessive quantities interfered with coagulation. This picture differs rather widely from that of hemophilia, whether idiopathic or icterogenic, for in the latter variety, as in the former, we have no evidence of any especial blood cell destruction. Moreover, as Quincke[17] points out, Rywosch's doses of the bile salts are larger than can possibly be encountered in the most intense icterus.

Lest I be misunderstood, let me mention, in passing, that cholemia, in which hemolysis or blood dissolution does occur, is by no means a simple bile poisoning; it may, indeed, be attended with little or no jaundice, and is, in fact, more akin to uremia, a mixed type of auto-intoxication, in which ptomains probably play the leading rôle. For obvious reasons I have here taken care to exclude the infectious forms of icterus from consideration.

The Scorbutic Diseases.—We now proceed to another group, including scurvy and its infantile variation, Barlow's disease.* In scurvy, in the course of a progressive cachexia,† we find extensive destruction of the blood cells, indicated by marked oligocythemia and oligochromemia; the bleeding is largely spontaneous, there is no very demonstrable failure of the blood to coagulate, a picture quite different from that of hemophilia.

There is, of course, no lack of theories, the weakest being again that of a bacterial infection, whose ablest sponsors (Babes[18]) do not seem to be fully convinced by their own very incomplete evidence, there being none, for instance, showing communicability. Wright's[19] theory of an acidosis has a better foundation, since the chemistry of the scurvy-producing diet points in that direction. The American Collective Investigation of Infantile Scurvy[20] proved that this disease is regularly associated with an unsuitable food supply, and disappears under a correct regimen. Experience had long ago led to the belief that an exclusive diet of certain artificially preserved foods is the primary cause of scurvy; in the abovementioned investigation, and in the recent discussion on Barlow's disease in the Berlin Medical Society[21] that fact was established beyond a doubt; evidently, under the circumstances, bacterial action cannot come into play, the deleterious change in the food must therefore be a chemical one. Further proof, that the scorbutic diseases are a form of chemical poisoning, is adduced by the very old and correct observation, that a simple change in the dietetic chemistry, namely, the addition of salts of the organic acids, is rapidly curative; it is also interesting to note how closely the symptoms of scurvy resemble those of chronic mercurialism. Incidentally, all observers agree, that anything like original or acquired immunity is conspicuously absent; this fact supplies further corroboration as to the type of intoxication presented.

Of the precise nature of the scurvy-producing poison we can as yet say little. In this case, as in others, the convenient designation of "ptomain" has been brought in to label our ignorance; as no ptomain whatever has yet been demonstrated, this view for the present must remain a mere guess. A possible theory rests on the old opinion of Garrod,[22] that a deficient supply of the organic salts of potassium causes scurvy, a sort of argument ex juvantibus; thus the cells would break

* The practical identity of scurvy and Barlow's disease is now generally admitted (21).

† Cachexia is in effect only the clinical expression of a chronic progressive blood cell disintegration, as seen, for example, in the "pernicious anemia" picture of the blood in carcinosis; analogous changes in the other tissues can hardly be of equal importance to the organism as a whole.

down from a kind of starvation, more accurately, perhaps, from an auto-intoxication by their own faulty metabolism. We are also bound to infer that the important salts in the food undergo the deleterious chemical change either through prolonged heating in contact with the food proteids, or through antiseptics employed in food preservation; both kinds of sterilization having been productive of scurvy. Although Garrod's theory as amplified remains purely empirical, it seems, nevertheless, to be the best we have; it is more than likely that we are dealing with a characteristic auto-intoxication due to an abnormal tissue chemism, a suitable readjustment of which promptly causes a cessation of the morbid process.

Where does scurvy belong in our general system of pathology? Evidently not to the type represented by hemophilia; on the other hand, it presents a considerable resemblance to a well-known non-hemorrhagic disorder. Referring, once more, to the infantile variation bearing the name of Barlow, we note that the discoverer himself regarded this affection as an acute form of rhachitis;[23] some authors still approve of this designation, but Ziegler's investigations[24] show a number of differences between the two, the chief being that in Barlow's disease the bone marrow is most implicated, in rachitis the periosteum. It must be conceded, however, that there are many evidences of relationship. The etiology of both is, after all, similar, namely, an unsuitable regimen; both also are successfully treated along similar lines, the causal indication being met by correcting the diet.* The more rapid result in scurvy is merely a repetition of a usual difference between acute and chronic diseases. It seems to me that scurvy and rickets unquestionably belong in one class.

The Exogenic Hemorrhagic Diseases.—The exogenic hemorrhagic diseases are readily divisible into three sections, on the basis of etiology, as we are here on fairly firm ground. The most rational and convenient division is into: (1) Chemical blood poisoning; (2) non-infectious toxinemia; (3) infectious toxinemia.

Chemical Blood Poisoning.—We have seen that there are numerous chemicals capable of causing blood dissolution and spontaneous hemorrhage; as I have already treated the subject somewhat in extenso, I shall discuss it now only in its relation to other groups. Toxic purpura, as I must designate this type, has been in a great measure surrendered to the dermatologists; a little excursion into their domain will furnish some data to aid us in the discussion to follow, provided that we employ them with that reserve, which deductions from poisons to toxins ought always to call for.

We have a characteristic series of blood poisons in our new friends, the antipyretics of the anilin group, of which acetanilid is an excellent representative; the liberal administration of these drugs has supplied us with a mass of invaluable toxicological material. Acetanilid, being a nitro-body, acts by converting the hemoglobin into methemoglobin, with the ultimate possibilities before stated. The cutaneous manifestations of poisoning with this substance consist in a great variety of dermatoses, the chief interest for us lying in the thereby demonstrated relationship among these eruptions. Most frequent are the erythemas, morbilliform and scarlatiniform, often becoming purpuric, in a smaller proportion vesicular, *i.e.*, herpetic or pemphigoid; very commonly the rash presents the appearance of an urticaria or the so-called angioneurotic edema, which, by the way, is neither neurotic nor an edema; for it is primarily of hemic, not of nervous origin, and does not pit on pressure; it is not the result of a venous stasis, but an inflammatory exudation.

At the commencement of this essay, I called attention to the difference between cell destruction and the impairment of cellular function by chemical poisons; in the blood these two processes are admirably illustrated by the respective actions of acetanilid and quinine, which produce symptoms clinically almost identical. Binz[25] showed that quinine interferes with the normal oxygenation of the hemoglobin, eventually resulting in the death of the erythrocyte. In the case of acetanilid the oxygenation is replaced by a firm oxidation, with the same ultimate consequence. Thus we see the same effect produced in two entirely different ways by two hemoglobin poisons; the greater gravity of acetanilid poisoning being inevitable from its effects being permanent.

The Non-infectious Toxinemias.—At the beginning of this paper I gave an outline of the action of the most typical and powerful of the blood toxins, namely, snake venom, and at this point shall merely add, that the various similar animal secretions, notably the venom in the bites and stings of insects, differ from it chiefly in degree, and that only apparently, if we consider quantitative relations. All these insect toxins produce urticaria, some even purpura; natural immunity is frequent, to acquired immunity all the residents of our mosquito infested swamps will readily testify. There is no occasion here to pursue the subject further.

Among vegetable toxins, we may, with some positiveness, place the noxious principles of nettles and poison ivy (Rhus radicans L.). Investigations in this direction are still needed, but the well-known frequent immunity to poison ivy is highly suggestive. In this connection the researches of Dunbar[26] are of the greatest interest and import; the pollen of certain grasses, golden-rod and ragweed are shown to contain toxins, producing in the symptom group of hay fever a characteristic intoxication of the urticaria type.

From the facts presented in the last two chapters, the conclusion is inevitable, that spontaneous hemorrhage, by itself, forms a most unsatisfactory basis for pathological classification. We

* Personally I have had no startling success with phosphorus in rachitis, and have always observed that the most ardent defenders of this most unpleasant drug have been the most insistent advocates of sound dietetic measures.

have found it impossible to draw a line between this symptom on the one hand, and certain erythemas, urticaria and herpes on the other. The evidence is overwhelming that all these correspond only to different degrees of the processes of blood dissolution and hemolysis, and we shall obtain further corroboration of this point in the chapter on the infectious toxinemias.

Before passing on to that branch of the subject, however, let me give a brief résumé of the theories of urticaria. Unna[27] attributes urticaria to a series of local venous contractions with secondary stasis and "edema," the unaccountable non-edematous character of which he seeks to explain away by calling it an "elastic edema." Now, in addition to this evasion, his theory includes at least two errors. First, there is no passive hyperemia present to cause edema; secondly, the author ignores the admirable provision for collateral circulation in the skin. Heidenhain[28] more correctly considered the exudation to be due to an inflammatory production of lymph, with increased activity of the vascular endothelium, caused by poisons in the blood. In addition, Philippson,[29] by injecting atropine and other blood poisons into the circulation, demonstrated that erythema and urticaria are both of hemic origin, differing solely in degree. Of especial interest to us is the observation of Ferré and Lamy, cited by Barthélemy,[30] that a temporary immunity to an urticaria-producing substance may be acquired through its repeated administration. These investigators attributed the phenomenon to exhaustion of the vasomotor nerve ends, but Ehrlich's theory now seems to afford a far better explanation.

The Infectious Hemorrhagic Diseases.—All the infectious diseases may be attended with hemorrhagic symptoms, not a very surprising circumstance considering that they are all more or less toxinemias. In typhoid fever and diphtheria hemolytic symptoms are relatively rare, in the exanthemata and the septic diseases they are more frequent, their intensity being usually fairly commensurate with the severity of the infection.

The so-called exanthemata, measles, variola, scarlatina, on the one hand; and the septic diseases, typhus fever, streptococcemia and rheumatism, on the other; have many features in common. Some authorities, indeed, would consider scarlatina, rheumatism, and ordinary sepsis mere variations of one form of infection; so far, however, most of the evidence is against them. The absence of reciprocal immunity and the failure of the anti-streptococcus serum in scarlatina* are decidedly adverse arguments. All that can be claimed, for the present, is that these affections have a marked resemblance to one another in their general symptomatology.

The infectious character of acute articular rheumatism has been suspected for many years, but only within the last decade has this view gained general acceptance. The type of fever, the occurrence of epidemics, the metastases, and last, but not least, the success of internal antisepsis, establish this theory quite firmly; all that we now require is the demonstration of a specific germ, and here, unfortunately, confusion still reigns. It must be admitted however, that the discovery of bacteria in the circulating blood is not necessary, they are not to be found there in some forms of unquestionable sepsis; we know that a toxinemia alone will produce all the observed symptoms, the presence of free micro-organisms is not essential. Various observers have found various germs in rheumatism, including those of ordinary sepsis. The increased coagulability of the blood and the marked anemia attendant on this disease have been noted for centuries, and in our time verified by the modern methods; Bussenius[31] demonstrated agglutinins in the blood; thus we have ample evidence of hemolysis.

The old view, that acute articular rheumatism is a specific joint affection, has been abandoned; we are now in position to say that this lesion is only one of the metastases of a systemic infection. Passing by endocarditis and pericarditis, I shall say a few words concerning certain less generally accepted phases of rheumatism. Amygdalitis is quite frequent in the course of rheumatism, and we have every reason to believe that many anginas occurring independent of articular inflammation are, nevertheless, rheumatic; endocarditis has repeatedly been observed to follow amygdalitis uncomplicated with any joint symptoms.

Muscular rheumatism has given the pathologists no end of trouble, at present, however, the opinion of Leube[32] is rapidly prevailing; namely, that acute polymyositis, including many cases of less widely disseminated muscular inflammation, is usually, if not always, truly rheumatic. The following clinical facts support this view. First, we occasionally see the combination of articular and muscular inflammation; secondly, there is the experience of many observers (Cheadle, Still[33]), who, like myself, have seen typical rheumatic endocarditis with chorea, in children who have suffered from appreciable joint pains, but have presented only a moderate muscular soreness and tenderness ("growing pains"); thirdly, we note the ready response of acute muscular rheumatism to the salicylates; lastly, we have the parallel between the nodes of rheumatic myositis and the subcutaneous nodules first described by Hillier[34] in the course of the articular affection.

In the case of chorea, the relation to rheumatism has become more and more generally accepted since the publications by Romberg and Henoch in 1846: the combination of rheumatism, endocarditis and chorea is so familiar that a detailed discussion in this place would be superfluous.

I have reserved the rheumatic lesions that will interest us most for the last; I refer to the dermatoses of rheumatism. In addition to the nodes of Hillier, these include various erythemas, herpes,

* I am aware that the authorities here disagree, sometimes violently; see the not very edifying discussion (Berl. klin. Woch., 1902 No. 52 et seq.)

urticaria, and the Peliosis rheumatica of Schönlein a most suggestive array in view of the preceding chapters.

The mere mention of Peliosis rheumatica recalls a maze of controversy only now being straightened out. Peliosis rheumatica is one of a series of disorders forming an old scientific battle ground, yet the matter in dispute seems to admit of easy adjustment. It has been customary to name the following clinical types: purpura or peliosis rheumatica, purpura simplex (without joint symptoms), purpura hemorrhagica (with internal bleeding), erythema multiforme, and erythema nodosum, not to speak of minor variations. This cumbersome scheme may readily be simplified. In the first place, we can rule out purpura simplex, which we have seen to be merely a symptom, attending the most diverse intoxications; purpura hemorrhagica is, of course, tautological, for every purpura is hemorrhagic, we cannot admit that there is anything specific about epistaxis, for example.

As to erythema multiforme and erythema nodosum, most modern writers, such as Kaposi[35] and Osler,[36] consider them forms of a single disease, which they rightly prefer to call erythema exsudativum, and class as a mere eruptive variety of purpura rheumatica. Strangely enough, so high and recent an authority as Jarisch[37] drew a hard and fast line between the two erythemas, and regarded them as different diseases, calling attention to contrasts in their respective morphology, etiology, localization and clinical course. In the matter of morphology, Jarisch's standpoint seems somewhat narrowly dermatological, we have seen that the apportionment of cutaneous symptoms among the various species of intoxications is most misleading. As to etiological differences, he would seem to beg the question, since those he himself gives are of no great moment. Referring to clinical facts, many observers, myself included, have seen both erythemas combined with purpura and joint effusion in the same subject at one time; it requires only a moderate number of such cases to make the position of Jarisch quite untenable.

Many authors, like Litten,[1] have selected the old term morbus maculosus as a suitable designation for the entire group; this name has, in a high degree, the faults incident to nearly all symptomatic appellations, namely, ambiguity and inaccuracy. In view of the fact, that we regard rheumatism to-day as merely a convenient name for a mild type of sepsis of undetermined microbic origin, it seems to me that no better term than purpura rheumatica can be selected to cover the entire series of hemorrhagic diseases of similar origin, which, besides, in so many respects, give evidence of being only unusual forms of true rheumatic metastasis. The above aspect of the case is sustained by the prevailing opinion held at the Third International Dermatological Congress (1896), to wit, that purpura rheumatica and the two erythemas are mere forms of one disease. The matter cannot be considered absolutely settled until determined by bacteriological research; for the time being, however, as we have the consensus of the great majority, it is certainly justifiable to take the position I have indicated.

Summing up, then, we find that hemophilia, congenital or acquired, is a toxinemia with secondary auto-immunization to a quasi-normal function; that the scorbutic affections are chemical auto-intoxications, hemorrhagic only because the blood is especially involved; and that the purpura rheumatica group is only a manifestation of ordinary rheumatism or sepsis. After this exposition of their very diverse nature, it seems clear that the old class of the hemorrhagic diseases has become obsolete, should be relegated to the domain of historic medicine, and cease to appear in our monographs and text-books to further puzzle the student and physician.

I add a few lines concerning certain rare and obscure types. As to Henoch's[38] purpura, that clinician's original description makes it certain that we are dealing with a form of sepsis. It has since that time been observed in adults as well as children, and Osler[36] does not hesitate to make it variation of our last group, with visceral manifestations. As to Weil's disease, acute infectious icterus, I mention it here chiefly on account of the recent suggestion of Leiblinger[39] that it also might be of rheumatic origin, an interesting example of the present trend of thought on this subject. Winckel's disease, melena neonatorum, paroxysmal hemoglobinuria, and allied clinical pictures must be regarded not as distinct entities, but as symptom groups; like the other outwardly similar conditions, they have been placed among the hemorrhagic diseases; their proper position is under the various heads of sepsis, congenital syphilis, malaria, auto-intoxications, and so on, according to the individual case.

MEDICAL PROGRESS.

SURGERY.

Operative Treatment of Chronic Bright's Disease.—This operation has won a great many admirers during the past two years in spite of the general belief, at first, that it could not possibly give more than temporary relief to this much dreaded disease. R. GUITERAS (N. Y. Med. Jour., Nov. 7 and 14, 1903) has collected 120 cases which have been operated upon for this condition. Some interesting points in regard to the rationale of the operation are discussed. Investigations upon dogs seem to prove that the anastomoses between the kidney vessels and the parietal ones is not so great as has been supposed by some. The anastomoses which do occur are found principally between the kidney and the wall of the abdomen upon which it rests. The fatty capsule seldom contains any blood vessels of any importance. It is, therefore, doubtful whether it is advisable to completely decapsulate the kidney. Furthermore it is found that after a few months another capsule is found just as strong and resistent as the first, and it is suggested now by many that the good results which are obtained by this operation may be referred more to the diminution of renal tension than to the increased blood supply to the kidney. If this is true, it would support the belief held by so many that the results are more or less temporary even at the best. From these reports which were received he concludes that chronic nephritis should not be operated upon till medical treatment has proven of no avail. The time for operation is when it is noticed that the process is advancing rapidly and we fear that the heart will soon be overtaxed. The best results have been obtained by operation upon a single movable kidney, the seat of chronic Bright's disease. The most unfavorable cases for operation are those of diffuse nephritis and when there is general anasarca with bad heart the operation should not be done. Where there is marked destruction of the kidney substance the patients may be relieved for a few weeks, but they generally fail again and die when the capsule begins to contract.

A Case of Spastic Ileus.—It was considered doubtful if intestinal obstruction could be caused merely by a tonic contraction of the intestines, but the case of D. PANKOW (Münch. med. Woch., Nov. 10, 1903) certainly admits of no other explanation. After a combined hysterectomy and nephrectomy, extreme meteorism and feculent vomiting appeared, and the patient seemed lost until an artificial anus brought unexpected relief. At the operation the descending colon was found contracted to the size of a lead pencil, the remaining intestines were enormously distended. The anus could not be closed before eight weeks, since all previous attempts caused a repetition of the symptom. The cause was probably the same as in pylorospasm secondary to peptic ulcer; local losses of substance caused by circulatory disturbances in shelling out the uterus.

Present Status of Subarachnoid Cocainization.—The enthusiasm with which the use of cocaine by lumbar puncture was greeted a few years ago was, for a time, most pronounced, but its employment now seems to be advised only by a few surgeons, and only for special reasons then. In spite of the reaction which seems to have set in against this method of anesthesia E. G. MARK (New York Med. Jour., Oct. 31, 1903) has investigated the results which have been obtained by himself and many other able surgeons in this country and abroad, and finds that the reasons for its disuse are by no means so important as is generally believed. In regard to mortality only one case has been reported that could legitimately be placed to the credit of cocaine. Several others have been reported, but in each case no connection could be traced between the cocaine and the mode of death. The disagreeable symptoms which sometimes follow its use are probably not due so much to toxic effects as to shock, and may follow the injection of an equal amount of salt solution. These symptoms are seldom more than transitory. No case of infection has been reported and hence this danger must be very slight. There is, however, one valid objection, and that lies in the fact that in some cases the analgesia is of too short duration for prolonged operative procedures, sometimes lasting less than thirty minutes. He has addressed letters to a large number of the most able surgeons in the country, and believes from the answers he has received and from his own experience the following conclusions are justifiable: (1) That the method is as safe as, if not safer, than general anesthesia; (2) that we may safely employ up to $^{48}/_{100}$ of a grain of cocaine without fear of toxic results; (3) that shock is decidedly less than that of general anesthesia; (4) that on account of the variability in the length of its analgesic action it is contraindicated in prolonged operations.

Surgical Interference in Hanot's Disease.—The type of cirrhosis of the liver, which has been successfully subjected to operation is the atrophic form in which ascites is a prominent symptom on account of the obstruction to the portal circulation. J. ROSENSTIRN (Med. Rec., Nov. 7, 1903) has operated upon two cases of hypertrophic cirrhosis, the first one as a result of a mistake in diagnosis and the second one intentionally. In both the omentum, gall-bladder and superior surface of the liver were sutured to the anterior abdominal wall, after scarification was done, and anastomotic channels thus formed between the parietal and portal circulations. Marked improvement occurred in both cases and, in fact, the symptoms have practically disappeared. The reason for this improvement is unknown, but a fanciful theory advanced by the author is that in this disease there is primarily a hypertoxicity of the intestinal blood, which in passing through the liver causes the new tissue growth around the biliary canaliculi. The liver is thus made more unable to cope with this toxicity of the blood brought to it, and the system is poisoned by a direct flow of a large quantity of this blood loaded with impurities passing unchanged into the general circulation. By compelling a part of it to follow this circuitous route it is believed that a part of the purification may be effected in this way, and less work be demanded of the liver cells themselves.

Colloidal Silver in Erysipelas.—Numerous favorable reports have appeared from France and Germany in regard to the use of colloidal silver by intravenous injection in various infective diseases. W. COLEMAN (Med. Rec., Nov. 21, 1903) has been using this remedy in several cases of erysipelas, and thus far has been surprised at the prompt and decided benefit which has resulted. Within a few hours there is usually a marked diminution of the symptoms with reduction of temperature, and in twenty-four hours the evidences of inflammation are frequently almost absent. He recommends

the use of from 5 to 10 c.cm. of colloidal silver being injected slowly and directly into any large vein, preferably the large ones at the bend of the elbow. No disturbing symptoms have resulted, except perhaps a slight temporary rise of temperature. The frequent use of this drug in various conditions has seemed to prove the harmlessness of it, and although too few cases of erysipelas have yet been treated to warrant any valuable conclusions, yet it promises to be, at least, an important adjunct to other methods.

Surgical Treatment of Gastroptosis.—The various measures recommended for gastroptosis are numerous, yet many cases are benefited but slightly after years of treatment. It is for this reason that D. HAMMER (Münch. med. Woch., Dec. 1, 1903) warmly advises gastro-enterostomy. Frequently the diagnosis is not absolutely certain; the symptoms may be so severe and the dilatation of the stomach so excessive that a pyloric stenosis suggests itself, but if the patient consents to operation, a clear idea of the pathological condition can be obtained. Medical treatment is troublesome and only possible with patients in good circumstances, the improvement lasts only while lavage, careful diet are continued, but with operation the cure is permanent and little risk is incurred.

Functional Renal Diagnosis without Ureteral Catheterization.—Renal diagnosis by means of ureteral catheterization and cryoscopy are considered too complicated and unreliable by F. VOELCKER and E. JOSEPH (Münch. med. Woch., Dec. 1, 1903) to admit of general use. The use of methylene blue would be ideal were it not for the fact that this dye is not evenly excreted since changed in part into a colorless oxidation product. In a series of experiments, iodide of potash was given and the bladder filled with a solution of peroxide of hydrogen containing starch. After introducing the cystoscope the discharge of urine, which became converted into a blue cloud, could be easily observed. Since the fluid became too dark for further observation in a short time, the authors continued their experiments and finally discovered an ideal dye in indigo-carmine to replace methylene blue. Injected in doses of 16 centigrams into the gluteal muscles, it is absolutely harmless and possesses the further advantage of being excreted solely by the kidneys. The excretion is absolutely uniform; it begins in 15 to 30 minutes, reaches its maximum after two hours, and then gradually disappears during the next ten hours. An accurate study of the action of both kidneys is possible even in cases where one cannot find the ureteral orifices and truly beautiful pictures are obtained with the cystoscope. The method fails only in cases of prolapsed uterus and vagina, since here the discharge of urine is into a cul-de-sac behind a prominent bar of tissue and hence invisible to the eye. In prostatic hypertrophy and uterine tumors much better results are obtained than with urinary segregators. One great value of the method lies in the fact that the actual amount of functionating tissue in each kidney can be estimated by observing the frequency of contraction and the size and color of the blue cloud, which rises in the colorless fluid. It is also possible to determine approximately the specific gravity of each urine by introducing solutions of known density into the bladder and then observing if the cloud rises or falls.

THERAPEUTICS.

Antistreptococcus Serum in Phthisis.—Tuberculosis as such gives a fair prognosis and most uncomplicated cases can be cured with proper climate and care. With the appearance of secondary infections the outlook becomes much more grave and an extended trial of the new antistreptococcic serum seemed in place, especially since streptococci are found in most cases. D. MENZER (Münch. med. Woch., Oct. 27, 1903) believes that all cases where heart and digestive tract are still in good condition are suitable. He begins with half a cubic centimeter of the normal serum and repeats this dose in four to eight days, according to the reaction. Gradually the amount is increased up to 2 to 3 c.cm. The best site of injection is the thigh or arm. In from four to six hours reaction sets in manifesting itself in headache and increased cough, and expectoration with abundant leucocytes and degenerated cocci and tubercle bacilli. Occasionally the latter are demonstrated for the first time during this period. The temperature rises up to 37.6° to 39° C., abundant râles are heard over the lungs and a slight increase of leucocytes can be detected in the blood. A marked improvement in the general condition of the patients followed in almost all cases.

Properties of Radium.—An interesting résumé of the properties of radium is found in the article by S. G. TRACY (Jour. of Adv. Therap., Dec., 1903). It appears that this wonderful substance is capable of emitting three kinds of rays: Cathode and Roentgen rays, and rays due to positively electrified true atoms. Their combined effect resembles the X-rays closely, but it takes a much longer time to take a photograph similar to a radiograph. It has been proved to the satisfaction of medical men that radium salts have a positive effect upon diseased tissue and even at this early stage it looks as if their use were indicated in lupus and other forms of tuberculosis, rodent ulcer and some cases of deep cancer in chronic skin disease, atrophy of the optic nerve and blindness from other causes. The radium rays give more promising results in these conditions than other rays.

Effects of Roentgen Rays on Animals.—If a small amount of radium bromide is allowed to act upon small mammals at a distance of 12 to 15 centimeters, marked emaciation, dermatitis and death will follow in about three weeks. The Roentgen rays are more active and kill white mice after an exposure of 5 to 19 hours, even before a dermatitis has set in. The autopsy on such animals is somewhat disappointing, according to H. HEINECKE (Münch. med. Woch., Dec. 1, 1903), since the spleen alone shows lesions. As these lesions point toward a destruction of red cells, the writer believes that the rays kill by their deleterious action upon the blood. Though death was equally rapid where the head was protected by lead foil, it is still possible that the central nervous system is also implicated, since the ganglionic cells were also found abnormal when stained according to Nissl.

Some Morphine Derivatives.—The effects of morphine, codeine (methyl-morphine), and dionine (ethyl-morphine) are of the same general nature, differing only in the degree of their manifestation. For example, following a lethal dose of morphine the sleep is profound and convulsive manifestations are late and of little importance, while after codeine sleep is light, and there are attacks of epileptiform convulsions during one of which death takes place. Both drugs cause slowing of respiration and heart and lower blood-pressure, but morphine much more than codeine. Dionine, the higher homologue, acts like an intensified codeine, producing more fleeting sleep, more intense convulsions, and more marked depression of respiration, pulse, and blood-pressure. The question then arises, Do the "apo" derivatives of these bodies form a similar pharmacological series? To determine this A. MAYOR and E. FONTANA (Rev. Med. de la Suisse Romande, Oct. 20, 1903) have made a comparative study of the hydro-

chlorates of apomorphine, apocodeine and apodionine. Apomorphine produces vomiting in man and certain of the lower animals. In the dog, in addition, it induces a dreamy condition followed by a restless delirium. Sometimes, especially in mental conditions, it induces somnolence in man. Apocodeine produces neither vomiting nor delirium, but on the contrary, causes purging, muscular weakness, and sleep like that from codeine. It was hoped that apodionine would show the effects of apocodeine in increased degree, and would prove a valuable purgative for hypodermic use, especially as dionine itself is not infrequently laxative. However, apodionine has been found to be less potent than apocodeine, and to have an action between that of apocodeine and apomorphine. Sometimes it purges, sometimes it induces vomiting, but it is too inconstant for employment either as purge or emetic. To the heart all three substances are depressing, and a number of cases of collapse from apomorphine have been reported. Death from toxic doses of the morphine derivatives is due to paralysis of respiration, but if artificial respiration be maintained the heart will continue to beat. If then the administration of the drug is continued, the heart finally succumbs from direct action on its muscle or contained ganglia. The quantity of morphine and its ethers necessary to thus overcome the heart is four or five times as much as will stop respiration, except for peronin (benzyl-morphine), which is so depressing to the heart that paralysis takes place with very slight dosage after paralysis of respiration. Of the *apo* derivatives under consideration the dose per kilo to stop respiration in the rabbit is for apomorphine 0.099 gm., and to stop the heart 0.115 gm.; for apodionine, 0.81 gm. for respiration and 0.130 gm. for the heart; and for apocodeine 0.054 for respiration, and 0.152 for the heart. Apocodeine is, therefore, least depressing to the heart and most depressing to respiration. This latter effect is less than that of morphine and greater than that of codeine. Apodionine, then, will probably be of little use in therapeutics, apomorphine will continue to be used as an emetic, and apocodeine will be employed as a sedative.

Treatment of Surgical Shock With Adrenalin.—Laboratory experiments apparently show that adrenalin by intravenous injection is a very powerful cardiac and vasomotor stimulant. Its clinical value in the human subject is, however, somewhat uncertain. The toxic dose for man is not as yet known, but it is probably several hundred times greater than that in which the drug is ordinarily given. EDWARD MARTIN and M. E. PENNINGTON (Am. Med., Nov. 21, 1903) have recently employed it in six cases of shock, all of which exhibited symptoms of impending death. They did not feel that the present knowledge of its powers or toxicity was such as to justify its employment in cases where there was any hope of recovery by other methods. In two of these cases the effect of the intravenous injections of adrenalin was immediate and unmistakable, the recovery from the operative shock being well marked, although both patients died from sepsis a week later. Because of the tendency to abscess formation at the seat of injection incident to the ischemia caused by strong solution, the dilution should be at least 1-10,000, when the drug is given hypodermatically. It is not probable that any effect can be expected from less than 2 c.c. of the 1-1,000 solution. It is also apparently safe to give an initial dose of the strong solution in 90 c.c. of normal salt solution. In cases of urgency adrenalin chloride should be given intravenously in a dilution of 1-10,000, quite slowly, so as to prolong the effect of the drug, and should be pushed up to 100 c.c. of the strong solution or until the heart responds clearly to its influence. The authors conclude that there is as yet no convincing clinical proof to the effect that the drug is as efficacious when used in man as laboratory experiments would lead us to suppose. The clinical evidence also suggests that it lessens the bacteriolytic power of the blood of man in a manner similar to that known to take place in animals, and its use in cases of infections should, therefore, be prastised with caution.

PHYSIOLOGY.

The Influence of Electrolytes on the Action of Amylolytic Ferments.—Inasmuch as the results obtained by many investigators with respect to the action of acids on salivary digestion, do not agree, S. W. COLE (Jour. of Physiol., Nov. 2, 1903) undertook an investigation into the question with the object of finding, if possible, an explanation of the discrepancies. He found that it is necessary to distinguish carefully between the action of saliva and that of ptyalin. In studying the action of saliva, one is actually studying the action of ptyalin as modified by the influence of the other varying constituents of saliva, such as sodium carbonate salts, mucin and other proteids. It might reasonably be expected that the influence of various conditions on the rate of action of the purified ferment does not correspond with their effect on normal or even diluted saliva. The author found that the action of dialyzed ptyalin on dialyzed starch is increased by the addition of very small amounts of acids and of the neutral salts of strong monobasic acids. The sulphates accelerate the action considerably, but not nearly so markedly as chlorides and bromides. In the case of the chlorides the acceleration seems to be due to the influence of the chlorine ion, all chlorides having about the same effect. The action, however, is decreased by the addition of larger amounts of acid (0.0007 to 0.0012 per cent. of hydrochloric), and by the neutral salts of weak monobasic, dibasic and tribasic acids. The following hypothesis is brought forward to relate these facts: The hydrolysis of starch by ptyalin is accelerated by the presence in the solution of electronegative ions (anions), other than hydroxyl ions, and depressed by the presence of electro-positive ions (kations), and by hydroxyl ions. The acceleration due to a negative ion varies with the nature of the ion, being greatest for the anions of strong acids, and least for the anions of weak acids. An optimal concentration of these anions can be reached, the further addition being without effect. The ferment is destroyed by a certain concentration of hydrogen ions. The effect of any electrolyte upon the rate of action is compounded of two factors: The acceleration due to the anion and the depression due to the kation.

Temperature Variation in Nocturnal Animals.—Having established the fact that the temperature curve in monkeys is dependent on the alternation of cycles of activity and rest, J. J. GALBRAITH and S. SIMPSON (Jour. of Physiol., Nov. 2, 1903) found it of interest to investigate the conditions which obtain in nocturnal forms. They discovered that the owl exhibits a temperature-wave the inverse of that in other birds. It was also noted that in comparing various birds the smaller the bird the greater is the diurnal variation and that the mean temperature of the female is, as a rule, higher than that of the male.

Protoplasmic Activity of the Renal Epithelium.—By injection of various pigments into the circulation, W. S. CARTERS (Jour. Amer. Med. Ass'n, Nov. 21, 1903) sought to determine the method of their elimination by the kidneys. His results indicate that pigments are excreted by a protoplasmic activity of the renal epithelium. They do not exclude the possibility of fil-

tration of some of the pigment through the glomeruli. On the other hand, when ammonium carminate is used the sections indicate that this is the case. It should be borne in mind that both processes may operate at the same time.

Influence of the Nerves Upon the Artificially Revived Heart.—To what extent the nervous mechanism regulating the heart-beat is capable of surviving somatic death, was the subject of an investigation by H. E. Hering (Pflüger's Archiv, Oct. 6, 1903). The latter had already demonstrated that if in a mammal after death the heart be perfused with defibrinated blood, it is possible for a long time to get positive results by stimulating the vagus and the accelerans. In the present series of experiments the author used hearts which had been resuscitated by means of an artificial circulation of Ringer's solution. He found that under this condition he could elicit all the various manifestations of the effects of the cardiac centrifugal nerves, namely, the slowing, pause and weakening associated with vagus stimulation, and the acceleration and strengthening accompanying stimulation of the accelerans. The longest period of completed vagus inhibition was observed in a dog's heart and amounted to seventy-five seconds. The author was able to corroborate the interesting results obtained by Kuliabko with hearts resuscitated a long time after death. Exceptional opportunities were afforded him to carry out his researches on the hearts of anthropoid apes. His results with hearts resuscitated a long time after death show that even then the centrifugal cardiac nerves may be aroused into activity and that the vitality of the accelerans lasts longer than that of the vagus. These results are of exceptional significance inasmuch as in the long interval following death there was no circulation of blood or of other fluid in the nerve-fibers, and inasmuch as one would expect that the labile molecules of the nerves would succumb long before the dissolution of the cardiac muscle. Of interest from other points of view are the results of two experiments which were negative. In the one there is seen the possibility of reviving the heart, although not the cardiac nerves, one and a half hours after death caused by strychnine poisoning following a long period of chloroform narcosis. In the other, also on an ape, the animal after having been inoculated with tetanus, was killed by bleeding and the heart removed and placed on ice. Fifteen hours later the heart was revived, but no effects could be obtained on stimulation of the centrifugal nerves. In one successful case, three hours after the death of an animal that had been inoculated with tetanus, distinct results were obtained by stimulating the vagus and the accelerans. In a more remarkable case, the heart of an ape was resuscitated after three successive intervals, namely, 4½, 28½ and 53 hours following death. In the course of the last interval the heart was twice frozen as hard as a rock. The vagus effect was obtained six hours after death, and the accelerans effect as late as fifty-three hours after death. This result would seem to cast some doubt upon the generally accepted doctrine that in the process of death the central and peripheral nervous systems are the first to succumb. The author taking into consideration the influence of the accelerans, which, as the above experiments show, survive that of the vagus, is able to submit the two following alternative hypotheses, namely, it is possible to rehabilitate the function of the cardiac ganglia fifty-four hours post mortem, in the course of which time the heart has been completely frozen; or at the end of this long interval the cardiac ganglia have long lost their capacity to function, the accelerantes acting upon the heart without the mediation of ganglion cells, and in this event, the cardiac ganglia could not be considered the source of automatic stimuli to the heart-muscle.

New Studies in the Suprarenal Glands.—In the course of investigations on the comparative anatomy of the suprarenal bodies, S. Vincent (Jour. of Anat. and Physiol., Oct., 1903) finds that the suprarenal capsule of mammals consists of two separate and distinct glandular organs, which are anatomically conjoined, but developmentally and physiologically quite unrelated. The cortical portion, representing one of the organs, is of glandular form and structure, but nothing is known of its function, and its development is the subject of some discussion. The other organ, namely, the medulla of the mammalian suprarenal, is part of the system of "chromaffin cells," which are found also in various places in relation to the sympathetic nervous system. Imperfect is the knowledge of the physiological significance of these masses of chromaffin cells, whether in the suprarenal medulla or wherever else they may be found. The consensus of opinion, however, among most recent workers is that they are developed from the nerve cells of the embryonic sympathetic ganglia (or from the original neural epithelium), and that they are, when fully developed, highly specialized secreting cells which manufacture and pass into the blood-stream a very powerful substance, whose function is to maintain the tone of muscular and other tissues throughout the body.

Experiments with Rennet and Anti-Rennene.—A series of investigations were prosecuted by J. McFarland (Jour. Amer. Med. Ass'n., Nov. 21, 1903), which confirm Morgenroth's discovery that the repeated subcutaneous injection of rennet into an animal is followed by the formation of an antibody inhibiting the action of the rennet. They show that properly prepared mixtures of rennet and anti-rennene give a specific precipitate, and show for the first time that the action of the anti-rennene is infinitely more powerful when the two are united and allowed to stand for some time, before being added to the milk, than when immediately added to the latter. This phenomenon is analogous to the interaction of venom and anti-venene.

A Chemical Study of Hibernation.—In pursuing a chemical investigation of the hibernating gland of the hedgehog, E. W. Carlier and C. A. Lovatt Evans (Jour. of Anat. and Physiol., Oct., 1903) confirm the remarkable fact that life during hibernation is maintained practically upon fat alone, a condition made necessary by the well-known inability of the animal body to store up a supply of nitrogen. If the hibernating animals had not acquired this power of living without a constant supply of nitrogenous food, hibernation would have been an impossibility.

Conditions Influencing the Diurnal Wave in the Temperature of the Monkey.—The proximity of relationship between the monkey and man, renders physiological observations on the former of peculiar interest. J. J. Galbraith and S. Simpson (Proc. Physiol. Soc., Jour. of Physiol., Nov. 2, 1903) find that the diurnal temperature variation in the monkey is considerable. The rise always occurs during the period of activity, the fall during the period of rest. The wave is independent of the room temperature. In one series of experiments the monkeys were kept in darkness during the day and in artificial (electric) light during the night, and they were now fed at 6 A.M. and 9 P.M.; their periods of activity and rest were thus reversed. This was done with the view of ascertaining how far the curve is influenced by the so-called "hereditary disposition." The result was a complete reversal of the wave within twenty-four hours of the change

in the periods. In order to investigate the relation of light to the occurrence of the diurnal wave, the monkeys were kept in total darkness for a week. The wave, greatly modified, persists for some days and then totally disappears. These experiments show that the temperature control in monkeys is less perfect than in man.

The Question Concerning the Existence of Cardiac Ganglia.—It had been discovered by H. E. HERING (Pflüger's Archiv, Oct. 6, 1903) that in a heart resuscitated by means of an artificial circulation of Ringer's solution the accelerans fibers retain their irritability a much longer time than those of the vagus. This suggested the alternative hypotheses, namely: Ringer's solution is capable of preserving or arousing the vitality of the intracardial ganglia for many hours after the death of an animal, or it is not capable of doing this. In the latter case the intracardial ganglia are not the source of automatic impulses to the heart-muscle, nor are they part of the circuit carrying impulses to the heart along the centrifugal cardiac nerve. In discussing the theoretical and experimental aspects of this problem, the author finds that the experiences of Langendorff, Langley and himself teach that preganglionic stimulation of the sympathetic nerve after the death of an animal has no effect at a much earlier period following death than postganglionic stimulation. The last has also found that the vitality of the vagus and accelerans outlasts that of the preganglionic sympathetic. Moreover, Ringer's solution is not capable of preserving or arousing the activity of the sympathetic ganglia. Besides, the intracardial apparatus can bear the condition of anemia much better than the extracardial sympathetic ganglia. These results lead the author to conclude that the intermediate nervous mechanism in the heart is not the same as that contained in the sympathetic ganglia outside the heart, and that in all probability, at least as far as the accelerans is concerned, the intracardial nervous apparatus does not consist of ganglionic cells, and that the latter are not the source of automatic impulses to the cardiac muscle in the adult mammal any more than in the mammalian embryo. The author had shown that the vitality of the accelerans outlasts that of the vagus. Among the many known poisons there is none which exclusively abolishes the accelerans effect, while there are many that abolish the vagus effect, leaving the accelerans unimpaired. This observation lends support to the view that the impulse of the accelerans reaches the heart muscle in a manner different from that in which the impulse travels from the preganglionic to the postganglionic sympathetic. Anatomy and physiology agree on this point: the accelerans is not connected with intracardial ganglia; but the vagus is thus connected, yet the impulse reaches the heart from the extracardial vagus in a manner different from that in which it passes from pre- to post-ganglionic sympathetic; or, on the other hand, the vagus is not connected with intracardial ganglia, the latter having, as His, Jr., has pointed out, a sensory or vasomotor function.

HISTOLOGY, PATHOLOGY AND BACTERIOLOGY.

Blood Examination in Scarlet Fever.—In about 15.5 per cent. of scarlet fever cases, G. JOCHMANN (Deutsch. Arch. f. klin. Med., Vol. 78, Nos. 3 and 4) could detect the streptococcus in the blood during life. The germs were identical in every way with the *Streptococcus pyogenes erysipelatos*. Examinations during the height of the eruption, on the first or second day, were always negative. Clinically the cases did not differ from other severe scarlatinas without bacteriuria. Another proof that the germs have nothing to do with the severity of the disease is offered by the fact that they were never found in the hyperacute cases. A positive blood culture renders the prognosis very grave; in general it may be said that death will set in one or two days after the invasion. Where the immediate cause of death was nephritis, cocci were encountered in as high as 50 per cent. At best the number of germs found is small as compared with the large number often present post mortem; yet there are many reasons to believe that an actual multiplication occurs during life. In some cases a blood-examination half an hour before death was negative and twenty-four hours after death strongly positive, which made it seem as if a migration occurred even after the circulation has stopped, but animal experiments showed that the abundance must be attributed solely to multiplication on an especially suitable medium. There is no question that septicemia plays an important part in scarlet fever, so important that occasionally the primary disease is entirely overshadowed. It would be a mistake, however, to bring streptococci into etiological relation with scarlet fever, since their usual site, the tonsil, occasionally does not harbor them, and in very many cases they are found here in abundance in health. The morbid processes of scarlet fever merely break down the natural barriers and permit of an invasion of the blood and the internal organs.

Glycogen in Fever.—The experiments of D. ROLLY (Deutsch. Arch. f. klin. Med., Vol. 78, Nos. 3 and 4) prove that glycogen disappears from the body in toxic fever, hunger, muscular exertion and artificial fever caused by cerebral injury. The liver is the first organ to lose its glycogen and since the temperature is highest here, it is probably due in great part to the destruction of this carbohydrate. If animals are rendered entirely free from glycogen, injury to the striate body will no longer be followed by fever; if, however, the animals are now fed with sugar, rise of temperature will again appear. Pathogenic microbes and their toxins cause fever, no matter whether glycogen is present or not. The increased excretion of nitrogenous bodies after injury to the heat center is not a direct result of this, but is caused by the increased combustion of animal tissue incident to the high temperature. With toxic agents the amount of nitrogenous excreta is much higher, since they themselves cause proteid dissolution as well as glycogen combustion. Fever in general, is thus accompanied by two parallel processes: a specific destruction of the proteid affected by the toxin and a central irritation acting upon the glycogen.

Blood in Malignant Disease.—Careful examinations of the blood so frequently clear up the diagnoses of cases which are otherwise obscure that it has been greatly regretted that more information could not be obtained from the blood of malignant diseases. E. N. CUNLIFFE (Med. Chron., Sept., 1903) has examined the blood of 90 cases of malignant tumors and finds that his results correspond in a general way very closely with former investigators. The most constant and characteristic feature is the decrease which takes place in the amount of hemoglobin and in the hemoglobin index. Decrease in the number of red cells is usually met with in advanced cases or in those complicated by hemorrhage, but many early cases show no diminution. Leucocytosis is the rule in malignant disease but may be absent in early cases and sometimes in advanced ones. The main factors causing leucocytosis are the occurrence of metastases, hemorrhage, cachexia, ulceration, and septic infection. Pyrexia has no apparent in-

fluence. Polymorphonuclear neutrophiles are usually increased in number and this may be so even in the absence of leucocytosis. Abnormal cells as normoblasts and myelocytes may be present in advanced cases.

Nature of Fatty Degeneration.—The following experiments of F. Fischler (Virchow's Archiv, Vol. 174, No. 2) prove that fatty degeneration is not caused by an actual conversion of cellular protoplasm into a fat but by deposit of fat from the circulation. A chemically pure soap was allowed to circulate through the kidney of a rabbit with glycerin, the animal then killed and serial sections made of the hardened organ. The endothelial cells presented a finely granular appearance, while the tubular epithelium was in a condition of acute degeneration. With sudan all the granules were stained intensely, the fatty deposit being most marked in the convoluted tubules of first and second order, less so in the cells of Henle's loop. The tissues in the neighborhood of vessels were most affected, especially where an artery and vein were present close together. The experiments are an evidence of active chemical changes in the cells as the soap was first split up and the fatty acids then combined with the glycerin to form fat, which took the place of the altered cellular protoplasm.

Pathogenesis of Blood Diseases.—It is still an open question whether connective tissue hypertrophy is a primary or secondary process in interstitial inflammation. An ingenious theory is advanced by S. M. Zypkin (Virchow's Archiv, Vol. 174, suppl.), which, when applied to blood diseases, greatly elucidates this obscure chapter of pathology. It has been observed repeatedly that low organisms respond to all kinds of irritation by proliferating; as best example, a certain infusorium may be mentioned, which, when infected with parasites, begins to divide until each descendant is almost free from germs. This same phenomenon may be observed more frequently in the vegetable kingdom; in fact, almost the entire plant pathology has to deal with hyperplastic processes. The higher a cell is organized, the less marked will this phenomenon be, and in the highly differentiated cells of the human organs, degeneration takes its place. The connective tissue, however, being low in the scale, even in mammals, will proliferate. Hyperplasia and degeneration must thus be looked upon as two processes which may be induced by the same toxin circulating in the blood, and which go on simultaneously. The blood-forming organs (spleen, lymph-nodes and bone-marrow) are built upon the same type, their cells occupy an intermediary position in that they are capable of both degeneration and hyperplasia. Thus, in recurrent fever, the former is the rule, in most other infectious diseases, the latter. The order of pathological events with any intoxication would thus be as follows: Degeneration of the specific parenchymatous cells (degeneration of liver and kidneys in scarlet fever); degeneration and hyperplasia of the lymphoid organs (swelling of the spleen in typhoid); finally hyperplasia of connective tissue (chronic nephritis after diphtheria, scarlet fever, etc.). Infection such as influenza, measles and smallpox, which rarely cause swelling of the spleen, are not often followed by chronic inflammation, since the third stage can hardly be expected where the second does not set in. Cirrhosis of the liver need not be accompanied by a splenic tumor, since the action of alcohol may be purely local upon the liver; if, however, very large quantities are ingested it also exercises a destructive action upon other organs and then the spleen will swell. What has been said of the spleen also applies to the lymph-nodes and bone-marrow, for in almost all cases with splenic tumors the marrow will be found hyperplastic and lymphoid marrow will take the place of the normal fat marrow in the long bones. In applying the above principles to the blood, we must look upon this fluid as an organ with the red cells as highly differentiated, parenchymatous cells, only capable of degeneration, as manifested by anemia, poikilocytosis, micro- and megalocytosis, stippling, etc.; and the leucocytes as lowly differentiated, interstitial elements, possessing the power to proliferate. The first effect of an irritant upon the blood would then manifest itself as chlorosis, simple anemia or pernicious anemia, where there is only a degeneration of the specific elements, though the last-mentioned disease may already belong to the second stage when the spleen and lymph-nodes are found swollen. Better evidences of the second stage are found in pseudoleucemia, where the erythrocytes show degeneration and the cells of lymph-nodes and spleen hyperplasia. Most cases of splenic anemia, including the first stage of Banti's disease, occupy an intermediary stage between pernicious anemia and pseudoleucemia, in that the proliferative changes involve the spleen alone and there is really no good reason to look upon Banti's disease as a separate affection, since there are also cases where splenic anemia is combined with myocarditis or interstitial nephritis, instead of cirrhosis. The third stage is represented by the various forms of leucemia; the increase of white cells here corresponds in every way to the hypertrophy of connective tissue in other organs. That all blood diseases are manifestations of the same pathological process in varying intensity is well demonstrated by the fact that they often pass over into each other and that transitional stages which were formerly classified with difficulty are common. The different varieties of leucocytes generally react differently toward stimuli; since the lymphocytes are more highly organized than the other leucocytes, it is easy to understand why acute leucemia is generally lymphocytic and why the lymphocytes increase first in every leucemia.

Ultramicroscopic Examination of Fluids.—The new microscope, which enables the detection of ultramicroscopical particles by lateral focal illumination has been put to the practical test in medicine for the first time by E. Raehlmann (Münch. med. Woch., Dec. 1, 1903), with most astonishing results. Solutions of various dyes were found to contain myriads of small particles, shining in their own color, in suspension. In mixed colors, the particles of all the ingredients could be identified, but occasionally new combinations were formed. A great future is promised for this discovery in the detection of contamination. Most histologists believe that animal tissues stain readily because they become impregnated with the dye, but it now seems more probable that the fine particles simply coat the delicate structures. Certain non-colored organic substances were then examined and it was found that albumin solution, though filtered three times, also contains the albumin in finest suspension. A new method of quantitatively estimating the amount of albumin suggests itself. In a one-per-cent. solution it is impossible to obtain details, since the particles lie too closely crowded; in a dilution of 1 in 100,000 they become distinct and are still visible when the amount of albumin is only two parts in ten million. Their size varies and the smallest are just visible as fine points. They are all engaged in active motion, which becomes less, the higher the dilution. In solutions of dextrin, gum arabic, glucose and lactose, particles of similar appearance are found. With glycogen they possess a characteristic grayish-white color, and a peculiar motion, which probably points to a special form of solution; as soon as a small amount of diastase is added they alter their characters immediately and appear like those of dextrin.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, JANUARY 16, 1904.

INSANITARY NUISANCES AND LEGAL PROCEDURE.

THERE is no doubt that great improvements will be effected in sanitary conditions in the near future by the feeling that those who neglect proper sanitary precautions are liable, criminally and civilly, for their negligence.

This principle will affect many people and many more actions than are usually considered to come under the head of those bound to maintain sanitary conditions. There are two things, for instance, that at the present time are attracting considerable attention and that undoubtedly are provided for by a definite statute of the penal code of New York State. These two are the failure of street railway and elevated railroad companies to furnish proper heating for their cars, especially during the rush hours when there is so much of additional drain upon their supply of electrical energy, and when sufficient power is not at hand to heat, as well as move cars. The other is the necessity for railroad companies to provide some other means for the disposal of the sewage inevitably connected with transportation facilities, than the crude barbaric method which now prevails, and which consists only of scattering excreta to the four winds of heaven, hopeful perhaps that somehow nature will care for it.

Section 385 of the penal code of New York State reads in part as follows: "A public nuisance is a crime against the order and economy of the State, and consists in unlawfully doing an act or omitting to perform a duty, which act or omission: (1) annoys, injures or endangers the comfort, repose, health or safety of any considerable number of persons."

According to this statute persons so doing are guilty of a misdemeanor and are liable to fine or imprisonment, or to both.

There seems no reason to doubt that this section will be construed by the courts in such a way as to cause railroads that permit the abuse of deliberately transporting passengers in cold cars, because of the company's failure to have on hand a sufficient supply of electrical energy for heating purposes, even at times of heavy business, to be adjudged guilty of a misdemeanor and liable, criminally and civilly, for their actions in the matter. That an action in damages would lie in such cases in favor of persons who either caught cold or whose health had been seriously disturbed by riding in such cold cars, there also seems no reason to doubt. It is a new application of legal principles to make the companies responsible in such cases. But then the whole question of the origin of disease not as an inscrutable dispensation of Providence, but as a result of the neglect of proper sanitary precautions, has come to be acknowledged only in recent years, and the rational method of establishing legal precedents is by suits for damages.

Every physician knows that many of the colds, and probably even such infectious diseases as pneumonia and bronchitis, are acquired as the result of exposure to cold under the unfavorable conditions of overcrowding that obtain in our street cars and public conveyances generally during the rush hours. Certain parts of the evils associated with the peculiar shape of New York and the necessities of transportation the companies cannot correct, but at least the proper heating of cars must be maintained.

The same section of the penal code would seem to cover very effectually the nuisance with regard to the scattering of excrementitious material along the roadbeds of our railroads which has recently been so deservedly called to public attention in the columns of a medical contemporary. There is no doubt in any physician's mind of the danger of this practice. Excrementitious material that is allowed to dry, to be then blown about by the wind may easily be carried into streams that sup-

ply drinking water, or even into houses in smaller towns to be deposited on food materials. Here again it is only in recent years that the danger of this procedure has been recognized, and there is little doubt that much typhoid has been in this manner distributed. The present crude system, however, of disposal of this material can readily be improved upon if the railroad companies really care to bring about an amelioration of existing conditions, and there is a crying need for reform. Like every other improvement, however, that affects public comfort but does not appeal to the financial department of a railroad, and neither adds to its earning power nor subtracts from its receipts, this change in present methods has not and will not come to actual consummation unless the companies are forced to it.

In New York State at least we should be in a position to secure this improvement without delay. The deadly car stove went after proper legislation. We seem only to need the enforcement of already existing legislation in the present case to enable us to get rid of the dangers of open water-closets in passenger coaches.

There seems then to be a legal remedy at hand in most cases of nuisances involving health even remotely, and there is only need of a few precedents in legal decisions to secure rights that now are wofully abused. If some of the wealthier classes would, when their illnesses are the result of these violations of statute, take the matter in hand precious safeguards for the health of the community could be raised up. Much of true charity can be thus accomplished without the dangers of pauperization or the waste in official salaries that so often discourage charitable impulses.

THE BENDS AND THE "SANDHOGS."

There is a great class of underground workers who because of their toiling in the darkness, are generally known as "human moles"; a select division of this class, whose members grub the soil from the bottom of caissons are known among their fellow-workers as "sandhogs." Under certain conditions, only partially understood, they suffer from a disease, one symptom of which is familiarly and jocosely known among them as the "bends"; a less graphic synonym is "caisson disease." Languages indeed draw their very breath from the vernacular of the proletariat.

Since construction work began on the new Manhattan bridge, five men have been killed by caisson disease. In the past it has not signified much whether a dozen or more sandhogs were paralyzed or perished, it was the usual and expected thing for them to suffer periodically from the colicky pains they called the "bends." A few sandhogs more or less did not matter either to the public or to the contractors. Recently, however, a more important person has succumbed, viz., Dolan, a masonry inspector, and much public attention has, as a result, been called to bear on the subject. The Department of Bridges finds itself unable to employ inspectors who are willing to work three hours a day at $10 because of the high rate of mortality. The last victim, it is stated, was examined by a competent physician prior to his undertaking the inspectorship, and entered the caisson apparently in perfect physical health. He died shortly after coming to the surface.

It is unnecessary to dwell at any length upon the etiology of caisson disease. It is well known that in bridge building and similar subaqueous operations, the caissons devised by Triger are in almost universal use. Pol and Watelle, who wrote widely on the physiological effects of compression, as observed on themselves, state that pains in the ears, slowing of the respiration and pulse, an increase of urinary secretion are among the first evidences of the response of the individual to the pressure. Certain muscular movements of a finer kind are impossible. They found themselves unable to whistle or to whisper. On the release of the pressure they experienced a sensation of cold dyspnea; the pulse rate rising from 55 to 85. These authors state that there is no danger in entering the caisson nor in a reasonably long continuance of exposure to the increased pressure, decompression being the real danger. Unless this be effected very slowly, sharp muscular pains may subvene, hebetude, loss of sensation, coma, deafness, blindness or sudden death—any or all may follow. Further local symptoms: swelling of the joints and a violent pruritus, known in the sandhog vernacular as the "fleas," have been described by Francois.

In 1866 Triger addressed a report to the courts in which he maintained that it was relatively easy to prevent caisson disease. The means suggested by him consisted in the use of woolen garments and in the proper manipulation of the lift-lock. Triger asserted that if seven minutes were allowed for decompression, the accident would cease. Eads, while building the St. Louis bridge, where he employed a pressure of $4\ ^{15}/_{100}$ atmosphere, concluded that the rapidity of the compression and decompression is a less important factor

than the prolongation of the sojourn in the caisson.

The pathology of the condition has been ascribed by certain writers to minute hemorrhages in the cord and elsewhere. Others, including Pol, Watelle and Hoppe-Seyler have accredited the condition to an escape of the gases from the blood and their return to the free state under the influence of sudden decompression. This does not affect the three gases of the blood equally. The proportion of oxygen is very little increased as the pressure is raised, that of the carbon dioxide remains constant. Paul Bert found the chief increase to be nitrogen. It is probably the liberation of this gas which gives the long train of symptoms familiar to all. It is of great interest that the paralyses almost invariably begin in the legs. The lumbar enlargement of the cord is affected more profoundly than any other.

Cohen states that the intensity of the accidents accompanying decompression depend (1) on the length of the exposure to pressure, (2) on the element of individual resistance, (3) upon the degree of pressure attained, (4) upon the rapidity of decompression. Bert advised that this be effected at the rate of from eight to ten minutes for each atmosphere, but some authors double the period.

All authorities agree that the only method of treating cases of caisson disease is by an immediate reestablishment of the pressure followed by a very gradual return to the normal.

Dr. Walter Bensel, Assistant Sanitary Superintendent of New York, on being asked what action the Board of Health proposed taking toward limiting this menace to the health of the caisson workers, replied that before any more extensive caisson work was undertaken within the city confines, steps would be taken for their protection. The use of suitable locks, which up to the present time has not been insisted upon, will be made obligatory. The present methods of decompression in the case of the Manhattan Bridge are crude to an astonishing degree. At the expiration of the hour and a half shift, sandhogs and inspectors simply swarm up the stand-pipe overlapping each other on the ladder. Here they stand for from one to three minutes and pass from 45 pounds pressure to 15. There is no suitable decompression chamber; no warmth, no ventilation. Until now, any type of man applying for the work has been allowed to qualify as a "sandhog." In future it is probable that only men under thirty and, so far as possible, those of a temperate habit, will be permitted to enter these ranks. In general, the department will suggest as preventive safeguards against caisson disease, first, adequate decompression; second, suitable ventilation and warming of the chamber.

Inasmuch as authorities agree that no symptoms whatever need develop in these underground workers, if proper care be given them, it is obviously the duty of the municipality to force contractors to exercise that care, even if it result only in the saving of a sandhog's life or in limiting his suffering from the "bends" or the "fleas."

THE ROLE OF THE PANCREAS IN CARBOHYDRATE METABOLISM.

WITHIN the past few months two papers have appeared in German journals which deserve more than passing consideration owing to their important bearing on the rôle of the pancreas in the carbohydrate metabolism of the body.

In the first by O. Cohnheim, it has been conclusively shown that, while neither muscle tissue nor pancreas are individually capable of causing glucolysis, both combined will cause such alterations in added glucose that this is no longer demonstrable by the usual reduction tests. Cohnheim concludes that the glucolysis is referable to the action of a muscle ferment which in itself is inert, but is activated by a second substance derived from the pancreas in a manner perfectly analogous to the action of enterokinase upon trypsin. The rationale of this arrangement is apparent at once, if we bear in mind that in the liquid muscle plasma ferment and kinase could scarcely coexist; some mechanism must hence be available by means of which the kinase is furnished according to demand. This function rests in the pancreas. The degree of glucolysis of which the muscle tissue is capable, on the basis of Cohnheim's experiments, is considerable, and in the case of a grown man would represent a minimum of 200 grams of dextrose.

The second paper, by R. Hirsch, of Hofmeister's laboratory, points out that a relationship exists between the pancreas and the liver which is quite analogous to that demonstrated for the pancreas and muscle tissue. It is to be noted, however, that the liver itself is capable of altering glucose so that it is no longer demonstrable with the usual tests. The degree of this hepatic glucolysis usually varies between 20 and 30, but may attain the value of 50 per cent. If, however, pancreatic tissue is added to the liver tissue the glu-

colysis is much more extensive and occurs with greater rapidity; the loss of glucose may then amount to fully 80 per cent. Hirsch accordingly draws the same conclusion from his experiments as Cohnheim, viz., that the pancreas most likely furnishes an enzyme (kinase), which activates a glucolytic hepatic enzyme, that in itself is inert. The apparently independent glucolysis of the liver he explains by the assumption that the fresh organ, only recently removed from the body, still contains a small amount of the glucolytic kinase, which activates a certain amount of the hepatic ferment.

Further experiments in this direction with animals that have been rendered diabetic by removal of the pancreas are urgently needed. It is interesting to note that in human diabetes several observers have found the liver devoid of all glucolytic activity (Jacoby, Blumenthal and Feinschmidt).

As regards the fate of the glucose, Hirsch has satisfactorily demonstrated that the organic acids, which are always formed during hepatic autolysis, are not referable to this source nor was there any evidence to show that the glucolysis was associated with alcoholic fermentation. He was unable to isolate any products of its decomposition. Cohnheim, on the other hand, states that he could demonstrate carbon dioxide.

One notable difference apparently exists between the results of Cohnheim and Hirsch, namely the relative rapidity with which the glucolysis took place in the pancreas muscle tissue experiments as compared with the pancreas liver mixtures. In Cohnheim's experiments the glucolysis occurred principally within the first twenty-four hours, while with Hirsch no change whatever could be demonstrated during this time; the glucolysis here reached its highest point only after eight days. This difference is no doubt partly due to the different technic employed, viz., Cohnheim's method of complete cellular destruction, on the one hand, which would lead to a complete liberation of the intracellular ferments, and Hirsch's ordinary method of mechanical comminution without material cellular destruction on the other.

The important bearing which both papers have upon the subject of diabetes and the probable rôle which the pancreas plays in the pathology of the disease, suggests itself at once and invites speculation. We forego this temptation, however, in anticipation of further experimental data which have been promised.

HARMONY IN NEW YORK STATE.

In the department of Special Articles the Medical News publishes this week two communications of more than passing interest to the profession in the State of New York.

Dr. McCormack pleads in his masterly manner for unification in our State and presents a plea for the County Society as a basis for the structure of the organized medical profession of the country. He tells us moreover, of the rapid strides that have been made throughout the United States in the matter of healthy organization, and to his plea for union and peace we offer a hearty amen.

That this unification is coming is made evident by the report of the Subcommittee of the joint committee of the New York State Society and the New York State Association, and we most cordially recommend to the profession of this State that this straightforward, dignified and thoroughly feasible plan of procedure be unanimously adopted at the next session of the New York State Society, now ready to assemble at Albany.

The profession in this State has long desired to be united. Here is the opportunity. Unite!

ECHOES AND NEWS.

NEW YORK.

Dr. Thomas Darlington, Commissioner of Health of the City of New York.

The Commissioner of Health under the new City Government of New York City, whose portrait we present this week, is evidently a man of broad and liberal sympathies and of excellent education, who has constantly shown himself deeply interested in the affairs of the community around him wherever he chanced to live and his years of residence in different parts of the country must surely have brought him in contact with men of all kinds and conditions and consequently have given him that experience so necessary for administrative ability—knowledge of men.

Dr. Darlington was born in Brooklyn, in what was formerly called Williamsburgh. He was educated in the public schools of this city and in the Newark, N. J., High School. Later he took a special three years' scientific and engineering course at the University of the City of New York, followed by a three years' course at the College of Physicians and Surgeons of New York, from which he was graduated in 1880.

He practised medicine at Newark, N. J., 1880-82; was then at Kingsbridge, New York City, until 1888; at Bisbee, Arizona Territory, until 1891; and returned to Kingsbridge in 1891, where he has practised ever since.

He was district physician of the Seventh District, Newark, 1882; visiting assistant at St. Michael's Hospital, Newark, 1880-82; surgeon to the New Croton Aqueduct Corporation, New York, 1885-88; to the Harlem Canal Improvement Works, 1888; surgeon to the

Copper Queen Consolidated, and other mining companies, and to the Arizona and South Eastern Railway, Arizona, 1888-91.

After his return to Kingsbridge in 1891 he took an active interest in the affairs of the immediate community with which he was associated. He did not hesitate to give his time to the local school board and ever since the organization of his school district has sat as a member of the board. This was no perfunctory performance of duty for the purpose of attracting popular attention, but he was always known as one of those who would take practical interest in every affair relating to the improvement of the schools and no detail of school management was too trivial to receive his serious thought.

While thus devoting himself to school work he did not neglect other philanthropic opportunities, for instance, during the coal famine of last year, he had charge of the distribution of the free coal supplies contributed to the people of the Bronx by George W. Perkins, of the firm of J. P. Morgan & Co. At the same time he did not fail in his duties to the profession, nor to his patients. He was a faithful member of a number of medical societies, which are mentioned further on. He contributed a number of interesting, some of them very valuable, articles to medical periodicals. In 1888 he wrote on Pneumonia for the *New York Medical Record*, and another paper was contributed to the same journal on The Effects of the Product of High Explosives, Dynamite and Nitroglycerin, on the Human System. This paper was founded on his experience as surgeon to the new Croton Aqueduct Corporation, which was at that time building the tunnel for New York's water supply from the Croton valley. He had seen and studied a number of illustrative cases among the men working in the tunnel.

As a result of this experience he also wrote the article on "Tunnel-Poisoning" for the reference handbooks of the Medical Sciences. Later on, when business interests and his health required him to spend some time in a milder climate, he wrote on The Climate of Arizona and the Effect of Hot and Dry Climates in Disease, which was read before a session of the Congress of American Physicians and Surgeons, held at Washington in 1891. Dr. Darlington has not confined his writing to the strictly medical periodicals and has occasionally written literary articles of scientific bent for the *Youth's Companion*, of Boston, and more purely scientific articles for the *Scientific American*, of New York. He also was an occasional editorial contributor on hygiene and sanitation for the *Mail and Express* and certain other newspapers. All this shows that he is a man of breadth of intelligence and facility of expression. It is no wonder that he was so highly recommended for the position which has come to him. Among those who personally interested themselves for him by recommendation were Right Rev. Bishop Potter, Rev. Dr. George Alexander, Rev. Dr. George C. Bliss, Rev. Dr. G. A. Carstensen, the Rev. Dr. John Campbell, and a large number of brother physicians, as well as many of the prominent politicians of the Bronx.

At the present time Dr. Darlington is connected with the New York State and County Medical Association, the State and County Medical Society, the American Medical Association, the Medical Association of Greater New York, the Harlem Medical Association and the American Climatological Society, of which he is at present the vice-president.

Until his appointment as Commissioner of Health he held the following hospital positions in the Greater City of New York: Visiting Physician to the New York Foundling Hospital, of which he was the President of the Medical Board for two years; Visiting Physician to the Fordham Hospital, to the St. John's Riverside Hospital, and to the Seton Hospital for Consumptives; he is consulting physician to the French Hospital.

Dr. Darlington comes of an old New York family and is a member of the Society of Colonial Wars and of the Tilden Club. He has always been prominent in politics and is one of the incorporators of the Jefferson Club. No interest of the neighborhood in which he lives fails to attract his attention, and accordingly he is a member of the Northside Board of Trade. With all this, he is a comparatively young man, being scarcely more than forty-two years old, and would seem to have the promise of a very brilliant future.

HEALTH COMMISSIONER DR. THOMAS DARLINGTON.

We wish him every success in his new position and have only to say that it distinctly spells opportunity and that a good administration in the Board of Health may have great potency for further political honors.

St. Luke's Hospital.—Drs. Walton Martin and Austin W. Hollis have been appointed on the visiting staff at St. Luke's.

Dr. Lederle Retained.—Commissioner Darlington has announced that upon his motion the Board of Health has voted to appoint former Commissioner Lederle as Consulting Sanitarian to the Board of Health.

Death Rate and Cold Weather.—The recent cold weather and the prevalence of influenza has been responsible for a large increase in the death rate, according to the records of the Board of Health. There were 1,635 deaths reported in the city during the past week, while for the corresponding

weeks in 1902 and 1903 there were 1,497 and 1,320 deaths respectively. The greatest increase was in the number of deaths from lobar pneumonia and bronchopneumonia, a total of 304, against 221 for the corresponding week in 1903, or 143 more. A great many of these deaths followed cases of measles and influenza. Last week 789 cases of measles were reported, as against 584 cases for the week previous, which shows that the wave is increasing at this time.

Report of Post-Graduate Hospital.—The nineteenth annual report of the New York Post-Graduate Hospital has just been issued. It is a neat little booklet of some 110 pages, printed on very good paper, contains a dozen full-page pictures of the staff, operating room, etc., a full account of its charities, cases treated and present needs, and is on the whole a rather de luxe affair as hospital reports usually go. Disbursements for the year amount to $121,850.91; the receipts show a total of $109,634.01, leaving a deficit of $12,216.90, "paid and to be paid by the New York Post-Graduate Medical School." The total sum received by the institution as legacies since 1891 is $33,141.29. The following gives an idea of the number of sick poor reached through its benevolent supporters: Number of patients occupying beds in the hospital during the year, 2,330; number of free patients treated in the dispensary, 19,346; number of free visits by patients to the dispensary, 76,936; number of free days of hospital care, 43,801.

New Doctors' Offices.—A movement is on foot to transform the Madison Avenue Hotel at Fifty-eighth street into a building for doctors' offices exclusively. It is proposed to have as tenants only members of the New York Academy of Medicine, or such others as may be approved by a committee composed of Academy members. The owners will make the building more attractive from a professional standpoint than similar buildings in other cities, provided that they have sufficient encouragement from the response that comes during the next fortnight.

The Spitting Nuisance Again.—Under caption of "Spot the Spitters," the *Commercial Advertiser* speaks editorially in its issue of last Saturday as follows: "Dr. Darlington of the Health Board deserves the hearty cooperation of every public-spirited person in the community in his crusade against the spitting nuisance. It is high time for a new crusade, for during the past few months there has been a recrudescence of this abomination, many old and incurable spitters, who were alarmed into temporary decency by Dr. Lederle's exertions to suppress their activities, having resumed operations in the street and elevated cars under the impression that the war was over. This is especially the case on the elevated trains, and nobody has ever discovered a guard interfering with the offenders.

"Dr. Lederle had printed in convenient little pads warning notices which passengers could carry in their pockets and hand to such persons who called public attention to their need of the elementary instruction in manners and decency inscribed thereon. It requires some 'nerve' on the part of the ordinary unobtrusive citizen, especially if he be small in stature and unskilled in the art of self-defense, to offer one of these slips to a muscular spitter, and it is asking a good deal of him to make the venture. It should not be necessary, in order to have the law enforced, that citizens should take upon themselves police duty."

The Governor's Message.—Among other things the Governor's message contains some paragraphs upon health matters. He says of juvenile delinquents: The complaints made as to the management of the Home for Juvenile Delinquents have brought about two investigations, one by the management and one by the State Board of Charities. Both investigations have shown mismanagement, and both demonstrate the need of immediate action. Peculiar in its character, with limited power exercised by the State, it seems to me that the time has arrived for a change and for the assumption of this work by the State. While it is true that the Fiscal Superintendent has power over expenditures so far as the approval of estimates is concerned, the management of this asylum is entirely under the control of a private corporation. With a board made up of busy men, it is largely in the power of its superintendent to dictate its policies. Although its support comes almost entirely from the State, its officers are without the pale of the Civil Service rules which govern every other State institution and its management is self-perpetuating. Situated upon land which, in the event of removal or discontinuance of the asylum, must revert to the city, the State is annually called upon to contribute for betterments. Its close proximity to the greater city does not permit that healthy outdoor life which would be possible in a rural community; besides, the frequent visitations by many who should be kept away during the period which these youths are confined, is not always conducive to reformation. Experience at Rochester has demonstrated the wisdom of many of these conclusions, and to escape these evils the State has recently consummated the purchase of a large tract of ground for the removal of the Rochester Industrial School. Expense should not be a matter of serious consideration if results can be secured which make possible more complete reformation. The prevention of crime is more desirable than its punishment. Punishment may not be necessary if the playgrounds of the tenement population of our great cities are made attractive. Parks are as desirable as law, and sunshine brings out the best of man's nature. Therefore if the State should replace the asylum at Randall's Island with a similar State institution at some nearby point in an adjacent county, it would be of advantage both to its inmates and to those who could thereafter make use of the grounds now occupied by it for recreation.

Charitable Institutions.—The more modern methods of treatment of insanity, the consequent increase in requirements have brought us to an anomalous condition. Notwithstanding the additional space in hospitals, we apparently have not added to the dormitory capacity of our institutions. This to the unmformed seems like overcrowding and unwise economies. During the past three years appropriations amounting to $3,170,000 have been made to meet these growing demands. In 1898 the capacity was rated at 20,656, and in 1901 it was reduced to 18,078. Thus it would appear that the State's ability to properly care for its insane population was lessened notwithstanding that large sums had been expended to increase the dormitory facilities.

During the past three years provision has been made for 5,147 new beds, so that if the old measurement of capacity of 1898 were in force we should have, when all changes are made, facilities for a population of 25,403. The present population is 24,187, with a rating in capacity of 23,825. From this statement it will be readily seen that under modern methods more cubic space per capita is allowed,

with resultant advantage. In every direction that which is for the benefit of the patient has been furnished. The total cost of maintenance for the year was $4.104.689.23. Better discipline prevails among the employes, and the increased pay for the nurses has produced results which more than justify the additional expenditures involved.

The Control of Consumption.—The *Times*, in a recent editorial note, makes the following comment on the tuberculosis problem. It is a good campaign document. At the anniversary meeting of the New York Academy of Medicine lately held in this city, Dr. W. Gilman Thompson made several statements of great and general interest. That which seemed best calculated to challenge inquiry was the following:

"Within the past decade in the State of Massachusetts alone the mortality from tuberculosis has been reduced exactly one-half."

In view of the fact that between 1890 and 1900 the population of Massachusetts increased from 2,093,889 to 2,855,346, a net gain of 791,457, this statement was so startling as to demand verification. This we have been at pains to make, and the official facts are as interesting as the generalization to which they relate. Between 1885 and 1902, notwithstanding the increase of population above noted, the number of deaths from consumption in Massachusetts shows a decline from 5,955 to 4,685. During the period of fifty years since 1853 the death rate per ten thousand inhabitants of that State has declined from 42.7 to 15.9. This is full of encouragement, and shows without argument the value of State medicine intelligently directed.

Dr. Alfred Hiller, in *Public Health* of London, showed in March last that the change which has been constantly going on in the lessening death rate from consumption constitutes one of the marked features of the vital statistics of civilized countries. If the present rate of decrease in the mortality from this disease is continued uniformly, consumption should wholly disappear from England within the next half century. The same rule applied to Massachusetts would appear to show that the disease will be extinguished in that State within even a shorter period. Its death rate from consumption during ten years, per 10,000 of population, has been as follows:

Years.	Death Rates from Consumption.
1893	23.1
1894	22.3
1895	21.9
1896	21.7
1897	20.8
1898	19.7
1899	19.0
1900	18.3
1901	17.5
1902	15.9

The "white plague" is obviously controllable, and its extinction will be a beneficent achievement of medical science. As Dr. Thompson showed in the paper referred to, comparable results are being attained in the conquest of many diseases. In 1853 the mortality from yellow fever in the districts where it prevailed was as great as from the plague in other countries. To-day it is exterminated in places which have been its home for centuries. Malaria is no longer regarded as the abiding curse of certain localities. Sanitary engineering and systematic mosquito extermination can redeem them, and are doing so. The time is not far distant when the standard of a country's civilization can be better judged by its vital statistics than by those of its trade or finance.

PHILADELPHIA.

Dinner in Honor of Dr. Mitchell.—Members of the Franklin Inn gave a dinner January 6 in honor of the President, Dr. S. Weir Mitchell. Poems were read by Dr. Mitchell and others.

Reorganization of Bureau of Health.—The first move in the reorganization of the department of Public Health and Charities has been made by appointing Dr. A. A. Cairns Chief Medical Inspector. The vacancy created by Dr. Cairns's promotion will be filled by Dr. Thomas J. Beatty, at present an assistant medical inspector. Dr. J. Howard Taylor, the former chief medical inspector, on account of age, asked to be relieved from the responsibility of that position, and will be made an assistant medical inspector. There are still 37 additional assistant medical inspectors to be appointed. Nearly 200 physicians have already taken the examination for these positions with the prospect that many more will enter the competition.

Physicians May Vary Charges.—The right of physicians to charge fees in accordance with their patient's financial standing has been upheld by Judge Ashman in a recent opinion handed down in the Orphan's Court. The Judge said: "In my opinion, a physician may fairly demand, as the exceptant admitted was his practice, a maximum and a minimum rate of pay, just as the circumstances of his patients shall seem to indicate will be proper. It is true that a physician is unlike a tradesman, who has different qualities and therefore at varying prices; he is bound in every case to give his best service. But it does not follow that this service is worth the same in every case. The moral distinction between the code of the doctor who in theory has but one charge and in practice two, and his ruder but more candid brother who declares at the outset that he has a maximum and a minimum charge, fades away on the slightest analysis into a play upon words."

College of Physicians.—At the annual election held on January 6, Dr. Arthur V. Meigs was elected president, and Dr. James Tyson vice-president of this society. The majority of the minor officers were re-elected.

Polyclinic Hospital.—The annual "Corporator's Day," held January 11, was signalized by the opening of the new nurses' home, children's ward, and private rooms, these being part of the extensive improvements made during the past eight months. The work of the Polyclinic is increasing yearly, the clinics last year averaging 326 cases daily, and 1,173 persons were admitted to the wards. In the accident wards over 7,000 cases were received. Three adjoining properties are owned by the corporation, and on these an addition to the hospital will be erected as soon as $75,000 can be raised.

White Haven Leads in Consumption Cures.—As a result of a recent thorough investigation of the White Haven sanatorium it is said that this institution shows better results than those of any other similar institution in the world. The investigation was made by Drs. Flick and Stanton of the Phipps Institute and the staff of the sanatorium. After examining the weight records, temperature charts, etc., each of the 103 patients was given a thorough physical examination. This showed that every one was

making progress toward recovery. The greatest progress has been made by the tent cases who remained in their accustomed place during the recent cold spell, though the temperature was 28° below zero. An exhibit will be made at the tuberculosis convention in Baltimore, January 25-28. No fear will be felt from comparison with the work of famous European institutions. Severe weather has caused suspension of work on the new buildings which, when completed, will make possible the accommodation of more than 300 patients.

Pennsylvania Hospital.—The oil painting of Dr. Thomas G. Morton presented to the Pennsylvania Hospital by a number of contributors was unveiled on January 11. The portrait was presented to the hospital by Dr. J. C. Wilson, on behalf of the Board of Trustees, and was accepted for the hospital by Dr. Arthur V. Meigs. Dr. Morton was connected with the institution for a period of forty years, many improvements and new buildings being added during this time as a result of his untiring efforts in its behalf.

Tropical Medicine.—The first public meeting of the American Society of Tropical Medicine was held at Houston Hall of the University of Pennsylvania on January 9, 1904. Dr. James M. Anders, a vice-president of the society was in the chair. A brief statement of the scope and workings of the society was made by the secretary, Dr. Joseph McFarland, after which the speaker of the evening, Dr. James Carroll, of the United States Army, and a former member of the commission appointed by the Surgeon-General of the United States to investigate yellow fever at Havana, Cuba, made an address upon "The Etiology of Yellow Fever." Dr. Carroll reviewed in an interesting manner the early researches upon the etiology of the disease, giving special consideration to the work of Fraire, Sanarelli and Finlay, then reviewed the work of the commission whose researches have now become world-wide, and resulted in the proof that we have no reason to believe that yellow fever is propagated by any other means than the bites of the mosquito known as *Stegomyia fasciata*. It is only the female mosquito that bites, therefore, only the female mosquito that becomes infected. The mosquito is able to impart the disease only after twelve days have elapsed since its own infection, and may retain the ability to infect after many months, providing it does not meet with destruction in the meantime. A description of the experiments made to show the infectiousness of fomites, seemed to exclude all possibility of yellow fever being transmitted directly. It was with pleasure that the speaker reported that confirmation of all of the work of the United States Commission had been given by the more recently appointed French Commission.

CHICAGO.

New Medical Journal.—The first issue of the *Journal of Infectious Diseases*, the new scientific publication endowed by Mr. and Mrs. Harold F. McCormick, has made its appearance. The journal has been established in connection with the Memorial Institute for Infectious Diseases, founded by Mr. and Mrs. McCormick in memory of their son, Jack Rockefeller McCormick, who died of scarlet fever. The new magazine is devoted to the publication of original investigations dealing with the general phenomena, causes, and prevention of infectious diseases, both of known and unknown origin. It is to be published at irregular intervals, as rapidly as the amount of available scientific reports permits. The publication costs some $15 a year; it is estimated that the endowment is about $375,000. The first number of the journal contains eleven articles by bacteriologists and pathologists at the Universities of Michigan, Minnesota, and Chicago, from the Massachusetts Institute of Technology, and from the Government Laboratory at Manila. The editors of the journal are Dr. Ludwig Hektoen, and Dr. Edwin O. Jordan, of the University of Chicago. Dr. Frank Billings is associate editor.

Effects of the One Delivery a Day of Milk to Consumers.—The Bulletin of the Health Department has this to say relative to the effects of one delivery a day of milk to consumers, which contributed to maintain the high death rate. The disastrous effects on child-life, threatened by the barbarous action of the Milk Wagon Drivers in refusing to make more than one delivery of milk a day, were largely overcome by the relatively cold weather of the summer by unusual effort in milk inspection, including the employment of an emergency corps of inspectors, known as milk scouts, and by an enormous development of the sterilized milk service fostered by the Woman's Club and Hospital Association. As a matter of record, the mortality of infants and young children during 1903 was lower than ever before known—8.8 per cent. less than in 1902, 9.4 per cent. less than in 1901, and 57 per cent. less than the average of the period between the two census years, 1890 and 1900. In 1891 the deaths of children under five years of age numbered 110.38 in every ten thousand of population; in 1903 they were only 41.7.

Mortality for 1903.—The total deaths for 1903 will number 28,940, including the 587 deaths from the Iroquois Theatre disaster, instead of the 28,353 given in the statement of mortality for the year. This will increase the death rate from 15.04 to 15.35 per one thousand. Deaths from violence were already more than 12 per cent. in excess of the average for the period since the census year 1900; but these 587 theatre deaths swell the excess to 41.5 per cent. over the yearly average of violent deaths. Even with this addition to the total mortality, the death rate is 6 per cent. lower than the yearly average since 1892, although it is 8.2 per cent. higher than that of 1901, and 5.3 per cent. higher than that of 1902.

New Training School for Nurses.—It is stated on good authority that the Cook County Hospital will soon establish a training school for its own nurses.

Resident Medical Director.—Dr. P. Maxwell Foshay, of Cleveland, Ohio, intends to locate in Chicago early in April, and will be the resident medical director of the Mutual Life Insurance Co., of New York, which has recently been opened here.

CANADA.

Smallpox in Cape Breton.—The smallpox situation throughout the island and county of Cape Breton is becoming very acute and the local health authorities are somewhat puzzled as to what action they shall take to prevent an epidemic of the disease. In several districts of the county the disease has already reached that stage and grave fears are entertained lest it should secure a footing in Sydney. At several places the railway stations have been closed for several weeks.

Appointment.—Dr. W. F. Langrill, Hamilton, Ont., who has been Medical Health Officer of that city for some years, has been appointed medical superintendent of the Hamilton General Hospital, to succeed Dr. McLaren. The salary is $1,800 per annum, and there were a large number of applicants for the position from local and outside physicians. The Governors of the Hamilton General Hospital have decided to cooperate with the Toronto General Hospital in their

endeavor to get the Ontario Government to increase the amount of the grants to the various hospitals of the province.

Dental Course to be Established at McGill University.—At a regular meeting of the corporation of McGill University recently, it was decided to establish a dental department in connection with the Faculty of Medicine. With this object in view certain of the professors of the existing dental college of the province of Quebec, at present not more than three in number, who are not members of the teaching staffs of other universities will be appointed by the governors, professors in subjects in the dental department of the Faculty of Medicine. It will be the rule also that all professors of the Dental Department shall together form the executive of the Dental Department, of which also the Dean of the Medical Faculty shall be ex-officio, chairman. The course of study shall be determined by the Executive of the Dental Department subject to the approval of the Faculty of Medicine. The University shall confer upon students who have completed the required course, and who have passed the required examinations, the degree of master in dental surgery (M.D.S.). Not less than one year after graduation as master in dental surgery, the degree of doctor in dental science (D.D.S.) shall be conferred upon such graduates as have either: (*a*) Presented at any time later than one year after graduation a satisfactory thesis, embodying original research, upon some branch of dental science, or (*b*) have at the completion of three years, passed satisfactorily an examination in advanced dentistry, the scope of which shall be determined by the Faculty of Medicine.

Laboratory for Queen's University, Kingston.—Queen's Medical Faculty have asked the Ontario Government to establish in that city a branch laboratory in connection with the Board of Health, for the examination of pathological specimens. Such a laboratory would be an immense benefit to Eastern Ontario. For instance, in order to get specimens tested free of charge, physicians in the east part of the Province of Ontario, have to send them to Toronto, where the Government laboratory is situated. If a branch were established in Kingston, the results would be secured much quicker. It is stated that this branch laboratory has almost become a necessity, and there is no doubt but what the Government will accede to the request of Queen's. It would be likely under the direction of Dr. W. T. Connell, professor of bacteriology and pathology in Queen's.

Some Interesting Observations on Life Insurance.—Dr. Andrew MacPhail, of Montreal, has been making interesting observations and investigations as to the liability to earlier death of persons rejected by insurance companies, as compared with the liability of those accepted. He took note of 5,115 applications, of which 409 were rejected cases, and then followed up so far as he could, the after record of the rejects. He traced 235 of them, of whom during fifteen years only 31 died, while according to insurance actuarial figures, had the 235 been "sound lives," no less than 25 should have died in that period. Dr. MacPhail's conclusions are that those who are rejected by insurance companies, as a rule, manage to live about the usual average. One reason for this may be that in consequence of life insurance rejection, an ordinarily steady man takes special care of himself.

Sanatorium By-Law Carried.—At the Toronto municipal elections, which were held in that city, Jan. 1, a by-law to raise $50,000 for the establishment of a municipal consumption sanatorium, was submitted to the rate-payers, the vote standing: For, 4,071; against, 3,822. This is somewhat significant, as all of the local papers opposed the passage of any such by-law, in view of the great and good work which had been accomplished by the National Sanitarium Association.

The Prevention of Tuberculosis in Montreal.—The Montreal League for the Prevention of Tuberculosis is issuing an appeal for funds to enable it to carry on the war against consumption in that city. The League needs money now to establish free consulting rooms and intends as soon as possible to erect a sanatorium on Trembling Mountain near the city, at which place the Provincial Government has made a grant of land for the purpose. The aims of this League are intensely practical, as they are dealing with every reported case. The League is under the patronage of the Governor-General, Lord Strathcona, Sir Louis Jette and Sir Wm. Macdonald, while the Hon. Senator Drummond is the President.

Typhoid Fever Epidemic in the Suburbs of Montreal.—There are now about 600 known cases of typhoid fever in the suburbs of Montreal, in Westmount, St. Henri and St. Louis. The hospitals of Montreal are obliged to refuse any more patients suffering with the disease. At the Royal Victoria there are 40 cases; at the Western, 6 cases; there are 15 in the Homeopathic Hospital; at Notre Dame, 13 cases; at the Hotel Dieu, 20 cases; at the General Hospital, 28. The one thing which these municipalities have in common which is not shared in by the City of Montreal proper, is the water supply. During the last two years the character of this water was severely assailed, but not the water alone, but the milk supply is being subjected to exhaustive and detailed examination. The municipality of St. Henri has requested the provincial Board of Health to make an analysis of the water and the result is awaited with a great degree of interest, as the Power Company which supplies the water, claims that it is not at fault.

GENERAL.

Berlin Hospital.—Berlin is to have a new municipal hospital with 1,700 beds. It will cost over $2,000,000.

British Journal of Children's Diseases.—This is the title of a new journal to be edited by Dr. George Carpenter in London. The first number appears in January, 1904. As European editor for *Pediatrics*, Dr. Carpenter has built up in this country, through this widely circulated journal, a host of well wishers. We cordially hope for the new venture, the only one of its kind in Great Britain, a glorious success.

Malaria in Istria.—The Austrian Government has undertaken to exterminate malaria on the coast of Istria. Several stations have been established at which quinine is furnished free, and patients are carefully screened so as to prevent mosquitos from spreading the infection.

Prize for Dr. Schleich.—Prof. Karl Schleich of Berlin has received from the University of Würzburg a medal and a 1,000-mark prize for the discovery of the Scheich method of making surgical operations painless.

First French Congress of Climatotherapy.—This congress will be held at Nice, during the Easter vacation, from April 4 to 9, 1904. Professor Chantemesse has been named president; the vice-presidents are: Professor Renaut, Lyon; Professor Grasset, Montpellier; Professor Calmette, Lille; Dr. Balestre, Nice. The discussions will bear on five questions: The climate of the French Mediterranean coast; reporting secretary, Dr. Chiais, Mentone. Adaptation of the individual to climate; reporting secretary, Dr. Manquat, Nice. Influence of the French Mediterranean coast climate on tuberculosis and tuberculous patients. The influence of climate on the French

Mediterranean coast on rheumatism and on those subject to rheumatism; reporting secretary, Dr. Moriez, Nice. Disinfection of towns; reporting secretary, Dr. Balestre, Dr. Camous, Nice. For particulars write to Dr. Hérar de Bessé, Secretary General of the Congress, Beaulieu-sur-Mer.

OBITUARY.

Dr. Edward A. Everitt died at his home in Burlington, Pa., Nov. 22, 1903, of angina pectoris; he was born August 11, 1831 in New York State. He attended lectures at Ann Arbor, Mich., and Albany Medical College, where he was graduated with the class of 1856. Dr. Everitt was a member of the Bradford Co. Medical Society and had been a resident of Burlington, Pa., many years.

Dr. James Ferguson, proprietor of the Central Valley Sanitarium died last week at that institution. He was sixty-two years old and unmarried. He had conducted his widely known institution twenty years.

Dr. Henry A. Chors, thirty-seven years old, was found dead in bed in his room at 108 Concord Street, Brooklyn, last week. Heart trouble is supposed to have been the cause of his death.

Dr. Cornelius E. Billington, for many years a practising physician in New York City, and the author of "Diphtheria and Its Treatment," died at his home, 85 Madison Avenue, on Friday from a complication of diseases. He was the son of Linus Billington, a Presbyterian minister, and was about 60 years old and single.

Dr. Charles G. Frowert, one of the best known physicians of Philadelphia, died suddenly last Saturday. He was born in Philadelphia in 1850.

Dr. Frank W. Shaw, thirty-eight years old, of 327 Greene Avenue, Brooklyn, died in the Seney Hospital, that borough, last week. Dr. Shaw was a native of Lockport, N. Y., and a graduate of the College of Physicians and Surgeons of New York of the class of 1889. For two years he was one of the staff of the Presbyterian Hospital. He was a member of the Kings County Medical Society and assisting visiting physician to the Seney Hospital.

Dr. George H. Hackenburg, a noted scientific man, who is credited generally with being the originator of the telephone idea, died at his home in Austin, Tex., on Friday night. He was eighty years old. In 1864 he wrote an article which was published in *Godey's Lady's Book*, making public his ideas of the principles of the telephone, which were afterward practically applied by others. The article attracted wide attention. He was at that time living in Ohio. He was born in Union County, Pa., and was a graduate of the Medical College of New York University. He practised medicine in New York State for several years and was a frequent contributor to magazines on scientific subjects. He moved to Texas in 1873.

Dr. Stuart H. Reed died Jan. 6 from pleuro-pneumonia, after a brief illness. He was born in South Carolina, Oct. 10, 1854, and was the son of the Rev. Edward Reed. When twelve years old he located at Coxsackie, N. Y., with his uncle, Alexander Reed. In 1874 he was graduated from Claversack Seminary of Columbia County, N. Y., and was graduated from Williams College, Williamstown, Mass., in 1878. In 1881 he was graduated from the College of Physicians and Surgeons of New York City. In September, 1882, Dr. Reed came to Madison, and was a member of the Board of Chosen Freeholders for Chatham Township. He was elected a member of the first Board of Councilmen, and served several years on the Board of Education. He was an active member of the Morris County Medical Society. He also served for a number of years as physician for the Board of Health of Chatham Township, and was at his death a member of the Commission of Appeals.

Dr. William H. Ireland died at his home, 330 Cooper Street, Camden, N. J., last Tuesday morning, aged sixty years. He was one of the oldest practitioners in Camden, and at one time served as County Physician for three years. He was born at May's Landing, and graduated from the University of Pennsylvania in 1867. He had been President of the County and City Municipal Societies, and a life delegate to the State Medical Society from the County Society. He was connected with various college societies, including the Alumni of Pennsylvania University.

SPECIAL ARTICLES.

HARMONY IN THE STATE.

New York, January 12, 1904.

The Subcommittee of the Joint Committee on Conference presents the following plan of consolidation of the Medical Society of the State of New York and The New York State Medical Association for the information of the medical profession of this State.

The plan is the result of much labor, legal investigation, and careful thought and attention on the part of the Committee; and the organization recommended for the consolidated corporation is one which is now in successful operation in thirty-two States of the United States. It is based upon the form of government of the United States, and care has been taken not to interfere in any way with the autonomy of county organizations, or with their property or other vested rights.

We respectfully urge the members of the profession to promote by all proper means the passage by the legislature of the proposed act prepared by counsel for the Committee, authorizing the consolidation of the Medical Society of the State of New York and The New York State Medical Association. The proposed Act will be introduced in the Assembly or Senate in due course, and, if passed, will authorize the consolidation upon terms to be agreed upon by the two corporations. The consolidated corporations will be known as the Medical Society of the State of New York.

Before the agreement for consolidation under the proposed Act will become operative or effective for any purpose, it must be authorized or ratified by the vote of each corporation at an annual meeting, or else at a special meeting of each corporation called to vote upon the agreement, and it must also be approved by the County Medical societies in affiliation with the Medical Society of the State of New York.

The agreement to be recommended by the Committee for adoption in accordance with the terms of the Act will contain provisions for giving effect to the following stipulations:

1. All assets and liabilities of The New York State Medical Association shall be transferred to and vested in and assumed by the Medical Society of the State of New York at the time of consolidation.

2. Expert accountants shall be employed to ascertain the assets and liabilities of each corporation, and their reports shall be submitted with the agreement for consolidation.

3. All members of The New York State Medical

Association in good standing at the time of the consolidation shall be admitted to membership in the Medical Society of the State of New York.

4. All members in good standing of the County medical societies now in affiliation with the Medical Society of the State of New York shall be admitted to membership in the Medical Society of the State of New York.

5. All members in good standing of The New York State Medical Association shall be admitted to membership in the County medical societies for the counties in which they respectively reside.

6. All members in good standing of the Medical Society of the State of New York shall be admitted to membership in the County medical societies for the counties in which they respectively reside.

7. The plan of organization, constitution and by-laws of The New York State Medical Association, with such modifications as have been agreed upon by the Committee, shall be adopted as the plan of organization, constitution and by-laws of the Medical Society of the State of New York.

8. The following proposition shall be submitted by referendum to the vote of the members of the consolidated corporation, namely:

"The principles of medical ethics of the American Medical Association, being suggestive and advisory, shall be the guide of members in their relations to each other and to the public."

9. The Medical Society of the State of New York will petition the legislature for the passage of such further enabling act as may be necessary, if any, to carry the consolidation agreement into effect.*

AN ACT

TO AUTHORIZE THE CONSOLIDATION OF THE MEDICAL SOCIETY OF THE STATE OF NEW YORK AND THE NEW YORK STATE MEDICAL ASSOCIATION.

The People of the State of New York, represented in Senate and Assembly, do enact as follows:

Section 1. The Medical Society of the State of New York, incorporated by or pursuant to chapter one hundred and thirty-eight of the laws of eighteen hundred and six, entitled "An act to incorporate medical societies for the purpose of regulating the practice of physic and surgery in this state," and continued by chapter ninety-four of the revised laws of eighteen hundred and thirteen, passed April tenth, eighteen hundred and thirteen, entitled "An act to incorporate medical societies for the purpose of regulating the practice of physic and surgery in this state," and The New York State Medical Asociation, incorporated under chapter four hundred and fifty-two of the laws of nineteen hundred, may enter into an agreement for the consolidation of such corporations, setting forth the terms and conditions of the consolidation and the mode of carrying the same into effect.

Each corporation, party to the agreement, may petition the Supreme Court for an order consolidating the corporations, setting forth in such petition the agreement for consolidation and a statement of all its property and liabilities and the amount and sources of its annual income. Before the presentation of the petition to the court, the agreement must be approved by a majority of the vote lawfully cast at an annual meeting of each corporation, separately, or at a meeting of each corporation separately and specially called pursuant to its by-laws for that purpose, and a certificate of such approval, verified by the president and secretary of the meeting shall be annexed to the petition.

On presentation of the petition, the certificate of approval and the consolidation agreement, and on such notice to interested parties as the court may prescribe, and after hearing such interested parties as desire to be heard, the court may make an order for the consolidation of the corporations on such terms and conditions as it may prescribe.

When the order is made and duly entered, the corporations, parties to the agreement, shall be one corporation under the name "Medical Society of the State of New York," which shall not be deemed to be a new corporation, but to be a continuation of the Medical Society of the State of New York, incorporated in eighteen hundred and six. A certified copy of said order shall be filed in the office of the Secretary of State. All the property belonging to the corporations so consolidated shall vest in the said Medical Society of the State of New York, which shall have all the powers, rights and privileges possessed by either corporation at or immediately prior to the consolidation, and which shall be subject to all of the liabilities of each corporation.

§ 2. This Act shall take effect immediately.

Respectfully submitted,

A. JACOBI,
GEORGE RYERSON FOWLER,
E. ELIOT HARRIS.

* This bill has just been introduced.

A PLEA FOR UNIFICATION AND UNIFORM ORGANIZATION.

BY J. M. MCCORMACK, M.D.,
OF BOWLING GREEN, KY.;
CHAIRMAN OF THE COMMITTEE ON ORGANIZATION OF THE AMERICAN MEDICAL ASSOCIATION.

To the Medical Profession of the State of New York:

AFTER correspondence on the subject with members of the Joint Conference Committee, and others, more especially on the Society side, I have been requested, as chairman of the committee which has had this work in charge from its inception, to prepare for publication an explanation of the plan of organization for state and county societies which has been so generally adopted in the last two or three years. As the plan was prepared and is recommended for universal adoption, is already in satisfactory operation in 32 states and in over 1,500 counties, and is likely to be adopted in nearly all of the other states as soon as their annual meetings occur, as the subject is one of interest at this time to every member and well wisher of our profession, and, more especially, as the preparation of the plan for general adoption, makes my committee as responsible to you for anything wrong in it as though we were members of your county and state societies, it seems entirely proper that the request should be complied with, and an attempt will be made to place beyond question the truth of the following propositions:

1. That existing professional conditions and estrangements are useless and senseless, that they are hurtful almost beyond calculation to both the profession and the public welfare, and that they are remediable.

2. That the plan of organization is based upon our system of civil government, that it was prepared with much care and unselfishness, and that it contains nothing untried, experimental or impracticable.

3. That the county society is not only the unit of the organization, but the source of all authority and power in both the state and national bodies through a representative delegate system, and it is also the only portal of entry to the entire society system.

4. That coincident membership has been an old and

perfectly satisfactory method in many states, is essential to complete organization, and that it is just and right. It would be as unfair to permit a physician to become a member of his county society and enjoy all the benefits arising from the labors of the state society, as to permit one to become a citizen of Ithaca or Troy, without becoming a citizen of the State of New York and bearing the burdens and responsibilities of the same.

5. That amendment of any part of the plan is purposely made easy and is controlled by delegates from, and responsible alone to, the county societies.

6. That the time has come for unification, and that, while union under a defective plan, which the joint body could modify and improve for the common good, would be far preferable to a continuation of existing conditions, the one now proposed has been found excellent and practical after full trial in other states, and, having been prepared away from New York contentions and controversies, it offers a basis for compromise honorable alike to both factions and to neutrals.

In order to establish these propositions clearly and satisfactorily, a brief history of this reorganization movement is necessary. From the very outset the magnitude of our task grew upon us. Although in name medical societies—city, district, state and national—existed without number, and medical machinery and high-sounding official titles were provided sufficient for the civilized world, membership in most of them was small and little more than nominal, and, outside of a few states and localities, the profession was so torn with dissensions that it was in chronic disgrace in its own and the public estimation, and in a large measure robbed of its power, by legislation or otherwise, to help either itself or the public, for whose benefit it was supposed to exist. Into a profession already so overcrowded that there was less room and remuneration for the average man than for clerks and skilled laborers, commercial medical colleges were annually turning loose thousands of new graduates, many poorly equipped for intelligent modern practice, and all of them without an hour's training in professional conduct, business methods, or the importance of society membership, in which all should have been drilled with the care due to subjects to become of so much importance as soon as they come to serve the public, and face the problem of earning an honorable livelihood.

As a result, largely, of such lack of training, we found that of the 120,000 registered physicians in this country, only about 30,000, one in four, had ever been members of any kind of society, local, state or national. Most cities were little better organized than the country districts, a large submerged element being often found within an easy walk of imposing medical and post-graduate schools, libraries and hospitals, who had long lost hope of advancement, looked upon their profession only as a doubtful means of support, while those in the higher ranks wrangled and slandered one another, and brought odium on all, and Christian Science and other forms of bald, naked quackery, took the cream of a patronage which a united, self-respecting and honored profession would have deserved and received.

It was soon found, however, that these conditions, deplorable alike to the profession and public, were not universal. In Alabama, for instance, under a model plan of organization there resulted a united profession, with over 1,500 of the 1,700 physicians members of the county and state societies. Medical opinion was sought for the guidance of law-makers, executives and courts, the profession was honored and independent, and quackery was unknown. Kentucky, striving for the same ends under less perfect methods, had had no itinerant or advertising doctor within her borders for ten years, and the profession was aspiring to its rightful place as a directing force in public affairs. In a dozen cities also, usually of the lesser rank in population, under similar influences, harmony, co-operation, and measurable prosperity prevailed, and was increasing.

Inquiry soon demonstrated that the personnel of the profession was much the same everywhere, and the difference in the conditions found were apparently entirely due to difference in methods of organization. After all proper allowance for personal equation in rulers, governments are liberal or despotic as determined by their organic laws, and, probably quite as much as with a nation, the constitution and by-laws of a medical society will set the compass and shape the policy which will largely determine the future for both itself and its individual members.

Influenced by such belief and considerations, my committee began its work four years ago by grouping these provisions for state and local societies which had resulted in the most effective organizations, and with great care made our first draft of a constitution and by-laws for submission to, and discussion by, conferences of leading men in the various medical centers where there was a reasonable degree of harmony. Later the improved draft was published in the medical press and in pamphlet form and given the widest possible publicity. As we were performing an important, unselfish and gratuitous public service for the common good, advice and frank criticism were cordially asked from all, and these came freely and helpfully, especially from the better organized states and cities.

With such assistance, and in the light of such criticism, keeping always in mind that the plan should be democratic and conform to our methods of civil government, with local self-government by the county societies as the central idea, a simple but comprehensive system was gradually evolved, almost ideal in its outline and possibilities, which, after full trial under the most diverse professional conditions, has proven entirely practical. It is so flexible that it can be as easily adapted to the Cook County Medical Society at Chicago, with 1,800 members, as to sparsely settled counties in North Carolina or California with ten members. Under its operations in one year in Michigan the membership increased from 560 to 2,100; in Kentucky from 390 to 1,000; in Tennessee, from 300 to over 1,000; in Missouri, from 400 to 1,500; in Arkansas, from 190 to 703, and in like proportion in every other state adopting it.

It is a thoroughly democratic and American plan, using these much abused terms in their broadest and best sense. As has been said, the county society is made the broad foundation and source of authority for everything, as well as the portal of entry to both the state and national bodies. If a physician stands well enough at home to secure membership in his county society, he is eligible for membership and for any position of honor or trust in the state and national bodies, and, if he loses membership at home, subject to the right of appeal, he loses out everywhere.

The house of delegates, the legislative and business body of the State Society, like the general assembly of a state, is composed of representatives from the county and district societies, and such delegates are freed from political influence so far as possible by making them ineligible for any of the offices within their gift, and they are responsible alone to the constituencies electing them. As they are in session but two or three days, in order to make the transaction of any business possible, unlike senators and representatives, they sit as one body. This gives a body small enough for deliberative work, and yet gives county societies remote from the place of meeting, and all others, an equal and

only an equal, voice in all business affairs, if only the delegates are in attendance.

Carrying out the same principle of local self-government, this house of delegates, made up directly from county and district societies, elects from the general membership the delegates who, in turn, compose the legislative body of the American Medical Association. As in the house of delegates of State societies, this being a small body, with its members carefully selected and made ineligible for any other position, with the terms of half the members expiring each year, so as always to have men of experience in it, and which can remain in session, if necessary, after the general meeting adjourns, it was hoped to provide a body in which the interest of the profession and of scientific medicines might be considered and promoted in the broadest way.

The question of coincident membership in county and state societies is one which should require little explanation in New York. It has given satisfaction in the association, and has, of course, been under the observation of the society people. You have also had ample opportunity to observe the results of it in the neighboring States of New Jersey and Connecticut, where it has been in operation for years. It has been long the practice in Alabama, with the result that about 90 per cent. of the profession are permanent members, as well as in Massachusetts, Pennsylvania and Indiana, and recently in a total of thirty-two States. It is only one feature of the work, but it is so important that any complete or systematic organization of the profession is impossible without it. Besides, the justice of it is beyond question. It would be as obviously unfair to permit one to join his county society and enjoy all the benefits of the State society, arising from its legislative, educational, and other expensive and responsible labors, without assisting in its support, as it would be to permit a man, if one could be found so foolish and selfish as to ask it, to become a citizen of Buffalo, Syracuse or Rochester, and enjoy all the benefits and protection of the state government, without becoming a citizen of New York.

It is true that in nearly every state where this plan of organization has been proposed, as was natural and to be expected, academic and purely theoretical objections have been made to some feature of it, usually to the council, the house of delegates, or to coincident membership. Such objection has always been made in advance of a trial of them, and they have been confined almost entirely to States which have been practically without organization heretofore. Conditions in Iowa illustrate this point well. The county society at Dubuque, which has reorganized and applied for a charter within the last ten days, raised many such theoretical objections to the plan before they had tried it, while 88 counties in the same state, organized under it, and realizing its practical benefits, are loud in praise of the very provisions to which their worthy neighbor at first objected. It is a source of much encouragement that this has been the experience of over 1,500 counties which have reorganized.

It would be pleasant to comment on each provision of the plan in detail if space permitted. Suffice to say that it was intended only as the foundation and frame work for a broad and comprehensive system to be recommended for universal adoption, that nothing was included except for what appeared the best of reasons, and that it is susceptible of infinite elaboration and improvement in detail as the profession of any state or county develops under the catholic and cooperative spirit which it inculcates, and which is so much to be desired.

Attention is called to the fact also, that much contained in the by-laws, where a wide departure is made from the brevity and compactness of expression adhered to in the constitution, is suggestive and educational in character, much of which would not be necessary if such an organization as is contemplated was already in existence. We thought it as important, under existing conditions of discord and demoralization, to furnish incentives to this work, to give practical and detailed information as to how it was to be done, and to put the reasons for it all within easy reach of those whose duty it would be to discuss the subject and do the work as to furnish the framework of which, as the result of years of devoted labor, they were to make a complete edifice occupied by a united and harmonious, or at least a decently cooperative and self-respecting profession. For many reasons, too, amendment to the plan is purposely made easy. If after trial in any state anything is found obsolete or impracticable, it can be easily eliminated or replaced by something better adapted to existing needs, by the house of delegates, subject to instruction from the county societies, at any regular meeting, after such amendment has lain upon the table for one day.

Unification in New York has been so long the dream and hope of its own profession, as well as of the entire country, that now, when this seems about to be realized, it may be that a majority of you will consider mere methods and details of organization important only in so far as they are likely to hasten or delay the union. In part, this view of the matter is both natural and correct. A cordial union under a defective plan, which could be modified and improved to meet the needs of the joint body, when there would be unity of purpose and interest for the common good, would certainly be far better than to perpetuate the two bodies, even with model organizations for both, with the strife, discord and loss of public respect inseparable from such conditions anywhere.

Still, if it can be shown, as the writer believes will appear upon the most critical investigation of what is now proposed, that it furnishes ready to your hands a plan of organization to which you may build and add with confidence in the results, and which will at the same time hasten unification by furnishing a basis of compromise between factions so long divided that suspicion and jealousy have become so much mental habits that neither will be willing to accept what the other proposes, it should, and I am sure will, receive respectful consideration at your hands.

In the era of good feeling and enthusiasm which must follow unification, under such a broad, liberal and comprehensive plan, which would give an equal voice and power to the individual doctor in every county, organization should and would make rapid strides, and the possibilities opened up to your profession, and then to your people, would be almost beyond conception. In the face of such possibilities, standing upon the threshold of such accomplishments, petty prejudices and personal interests appear so insignificant that they should find no place in large minds.

Then, as New York would be in perfect alignment with her sister States, with proper education and effort, everything desirable would, in time, be brought within reach of the united profession of the entire Union. The complex and difficult problems before the profession of this country incident to our unprecedented advance in population and civilization, and which must be solved by it, if they are to be solved, will tax its highest intelligence and energies at its best. Provision can then be made for continuous scientific research, and for systematic collective investigation into the causes and prevention of diseases, upon the large, generous lines de-

manded by the vast interests involved. The vexed problem of medical education can then be taken up with confidence and justly and wisely solved. Reciprocity in licensure and membership between states can then be discussed from the standpoint of the common good and settled upon some equitable basis. Constructive statesmanship can be substituted for the narrow, time-serving political methods of the present in municipal, state and national public health affairs, and our great profession, great even now in spite of its divisions, united, elevated and ennobled, would come to occupy its rightful place as one of the greatest of modern forces for the guidance and protection of our people. It would be an honor, even to New York, to lead in a reform promising such results, and to set an example in complete organization, which less favored and weaker States would imitate with both pride and profit. First of all, leading to all and above all, in the words of your victorious commander, greater in magnanimity even than in war, "Let us have peace."

CORRESPONDENCE.

OUR LONDON LETTER.

(From Our Own Special Correspondent.)

London, December 19, 1903.

HERBERT SPENCER—MEDICAL EDUCATION IN LONDON—THE ORIGIN OF CANCER—THE SERUM TREATMENT OF TUBERCULOSIS AND MALIGNANT DISEASE—DOCTORS IN PARLIAMENT.

Herbert Spencer, whose remains were cremated at Hampstead a few days ago, taught the world more by his life than by his philosophy. In spite of the indifference of a public which cared for none of the things he had to say, ill health, which made intellectual work at all times difficult and often impossible, and limited means, he struggled against adverse circumstances and finished the gigantic task to which he had given his life. His endeavor was the noblest that could animate a man, and it is a pathetic illustration of the futility of so large a part of human effort that his work was in great measure a failure. It may indeed be said that his philosophy died before himself. This is the usual fate of systems. Huxley put his finger on Spencer's weakness when he said that if the author of *Synthetic Philosophy* wrote a play the catastrophe would be the killing of a large induction by a fact. Spencer was an intellectual force of the first order, but his strong individualism led him in more than one direction into the company of "cranks." His utterances on medical matters betrayed a distinctly hostile bias which was difficult to reconcile with his general attitude toward science. He advocated free trade in the practice of medicine and seemingly had persuaded himself that the enforcement of regulations against certain infectious diseases was an unwarrantable interference by the State and a form of protection that could find no excuse in the eyes of political philosophy. But it was not only from this point of view that he condemned vaccination. In his very last book, Facts and Fallacies, published two or three years ago, he revealed himself as an "anti-vack" (*sit venia verbo*—it is Jenner's own) of the most virulent type. If he does not in good set terms denounce vaccination as responsible for cancer, consumption and many other diseases, he hints that by producing some mysterious change in the constitution it may lead to all kinds of mischief. He had evidently not studied the matter seriously, or his study had been singularly fruitless. In any case the fact that he should have written such nonsense on a subject as to which easily verifiable facts lay close to his hand scarcely encourages us *jurare in verba magistri* when he is dealing with more recondite things. The medical profession itself he looked upon with jealousy, if not dislike, as a close corporation, still retaining much of its primitive priestly and occult character. But with all his prejudices and limitations he was a man who, according to any right estimate of values, was the chiefest glory of his country. To our shame be it said, the vast majority of his countrymen knew little and cared nothing about the great philosopher. On the day the announcement of his death appeared on the bills of the newspapers, a porter at Charing Cross Station was heard to ask his mate "Who 's this 'ere Spencer wot 's dead?" The answer was "Why 'e's the man wot 'ad the balloon at the Crystal Palace!" The London correspondent of *Le Journal des Débats* relates that he was not long ago in company with some Englishmen and foreigners. The conversation turned on great men, and one of the Englishmen bewailed the fact that his country at the present time had none. One of the foreigners pointed out that she had at least two—a great philosopher and a benefactor of mankind who could stand comparison with Pasteur. The Englishman, evidently much surprised, asked who they were; and he did not seem to be greatly enlightened when he was informed that they were Herbert Spencer and Lister. I remember when Lord Lister was made a peer of the realm, hearing that one of the so-called leaders of Society, *une grande dame de par le monde*, as Brantôme would have called her, on seeing the announcement in the list of honors, asked who on earth the man was, and what he had done to entitle him to such a distinction! In this enlightened country, unless a man is a politician, an athlete or an actor, he need not expect that his name will be familiar in men's mouths as a household word. W. G. Grace, the cricketer—himself, by the way, a member of the medical profession—is far more famous than any man of science or letters in the kingdom.

An appeal has just been issued by the Senate of the University of London for funds to build and endow an Institute of Medical Sciences under the control of the University. Among the signatories are Lord Rosebery, the Chancellor of the University, Dr. Pye-Smith, Consulting Physician to Guy's Hospital, Vice-Chancellor, and Mr. H. T. Butlin, formerly surgeon to St. Bartholomew's Hospital, Dean of the Faculty of Medicine. The function of the Institute is to be the teaching of physics, chemistry, biology, anatomy and physiology—in a word, it is proposed to centralize the teaching of the sciences that form the foundations of scientific medicine. At present these subjects are taught in each of the eleven schools attached to metropolitan hospitals—a system that obviously makes for inefficiency. The necessity of concentrating the teaching of the subjects mentioned in one or two large institutions was strongly urged by Huxley more than thirty years ago, but the rivalries of the schools have up to the present time prevented the accomplishment of the reform. Now several of the hospital schools are on the verge of bankruptcy owing to the expenditure required for laboratories, apparatus and practical teaching. In order to keep them going subventions have to be made from the hospital funds. This gives an opening for attacks by the antivivisectionists who call on the public, not to subscribe to hospitals whose funds are used for the "torture" of animals. It is to be hoped that the money will be obtained, but I fear it will be difficult to persuade the British public to contribute toward the cost of medical education. It would be useless to ask help from the Government, which has the fear of the voter ever before its eyes.

Reference was made in my last letter to a remarkable

paper on the structure of the cells in Malignant Growths, which was read before the Royal Society last week by Professor Farmer, Mr. Moore and Mr. C. E. Walker, all of the Royal College of Science. Owing to the stringent rules of the Royal Society as to publication, it was impossible then to obtain even the briefest outline of the paper. The following abstract, made by one of the authors and revised by the others has since appeared in *The Times* (December 14) a paper which is privileged to be chosen by the officials of the Royal Society as the medium of publication of the communications which they consider to be specially important. As the paper has not been published elsewhere, the following summary of the work of Farmer, Moore and Walker may be interesting. Their investigations, it is claimed, have revealed a striking resemblance between the formation of sexual reproductive tissue and that of those abnormal growths in the higher animals which possess the property of invading and destroying the surrounding tissues of the body. These growths or tumors are, when occurring in man, known as "malignant," and include carcinomata (cancer) and sarcomata. The authors have rejected the hypotheses as to a parasitic origin of the disease, and also the views advocated by Cohnheim, according to which the growths are due to awakening activity in nests of "embryonic tissue" abnormally persisting in the organism after the embryonic stages have been passed. The changes which occur in cells that are about to produce reproductive or germ cells are highly characteristic, differing very materially from the changes observed in cells which are producing, or destined to produce, the ordinary tissues of the body. These differences are specially noticeable in the mode in which the nuclei of the cells divide, its nucleus passes through a series of changes, of which one of the most remarkable is the appearance of a number of rod-like bodies known as chromosomes. The number of these chromosomes is constant in each species of animal and plant, and does not vary during subsequent divisions so long as only ordinary body tissue is produced. In reproductive (not "embryonic") tissues, however, the cells, at a certain stage, undergo a special and very characteristic form of division, in which the chromosomes present a different appearance, and reappear in only half the number proper to the species to which the particular organism belongs. The descendants of these cells retain the reduced number of chromosomes in subsequent divisions until they finally produce those germ cells to which they normally give rise. When two of these germ cells fuse, the resulting cell (fertilized egg) again gives rise to a new individual, the cells of which possess the normal number of chromosomes. The authors have identified, near the growing edges of malignant growths, cells which are quite similar to those occurring normally in reproductive tissue, and they regard the conversion of previously normal cells into tissue which has assumed the essential features of reproductive or germinal tissue as being the immediate cause of the malignancy of the new growth. It is to be particularly remarked that the authors describe the tissue as being germinal and not embryonic, for in the latter the nuclei do not possess a reduced number of chromosomes. Cells which thus originate (as germ cells) exhibit in the normal life history of an organism that independence of growth and parasitic mode of nutrition that distinguishes malignant growths. The changes indicated have not been observed by the authors in benign tumors or ordinary inflammatory tissues; hence it would seem that they may be used as diagnostic signs, differentiating malignant from benign tumors. Naturally, in the case of tissues thus produced, the further history of the cells continues along abnormal lines, partly, no doubt, because of nutritional derangement. The causes that produce a germinal tissue from the normal cells of the body must doubtless be sought among physiological stimuli. Some of these are known to derange normal functions and to produce changes of form and structure. The authors believe that they are on the track of a method of what may be called physiological treatment that will prevent the development of malignant growths.

Marmorek's antituberculous serum, which has failed to find favor with the French Academy of Medicine, is being tried in St. George's and the Brompton Consumption Hospitals, by Dr. Arthur Latham, winner of the first prize offered by the Advisory Committee of the King's Sanatorium, for the best essay on the construction of sanatoria. He is to have the benefit of the personal advice of Dr. Marmorek who intends to visit London once a month to supervise the treatment. Dr. Marmorek was till lately on the staff of the Pasteur Institute, but the way in which he brought his serum to the notice of the public led to a protest on the part of his colleagues, and finally to his resignation. His serum has been tried by various well-known physicians and surgeons in Paris, with unsatisfactory results. Dr. Latham's report will be awaited with no very eager expectancy. It may be mentioned that his relative, Professor Latham, of Cambridge, two or three years ago undertook to investigate the effects of *Lachnanthes*, which is said to be the basis of a quack remedy largely advertised in this country. A preliminary report to the effect that no particular result had been observed was published some time ago. As far as I am aware no further report has yet appeared, and it is by no means unlikely that nothing more will be heard of the matter. At the Middlesex Hospital several cases of cancer are under treatment with a serum prepared by Dr. Otto Schmidt, of Cologne, with which he says he has completely cured some fifty cases. Of these at least three are known to have ended in death, and *post-mortem* examination proved that the cancer was not cured. The cases in the Middlesex Hospital were selected with the approval of Schmidt himself, but although they have been under treatment for more than a fortnight no appreciable effect has been produced.

Dr. Rutherford Harris, the first Secretary of the British South Africa Company, who has just been elected Member of Parliament for Dulwich, began life as a medical practitioner. He went to South Africa in search of health and there made the acquaintance of Cecil Rhodes who had a marked liking for doctors. Dr. Harris was for several years closely associated with Rhodes in his financial and political schemes. He will not count for much as a representative of medicine in the House of Commons, but the number of doctors in Parliament is so small that every addition to their ranks is welcome. The pity of it is that, few as they are, they cannot be got to act together in regard to legislation affecting the medical profession. An attempt has recently been made by the British Medical Association to induce them to form themselves into a Medical and Public Health Committee of the House of Commons. This might be a good thing in itself, but it is unlikely that the medical Members of Parliament will consent to act as delegates of the British Medical Association. It has been suggested that the Association should find doctors prepared to come forward as candidates for Parliament, should pay their election expenses and should provide an income for them while they sit in the House. It would be the business of these representatives to "assert the wants of the profession, in season and out of season." The Association might not have much difficulty in finding candidates, but it would not be so easy to find them

constituencies. As a political force, the medical profession in this country is a negligible quantity. This is perhaps not altogether to be regretted in view of the fatuous suggestion to which reference has been made. It is certain that if by any chance the British Medical Association were to succeed in getting a number of medical men who would be virtually its delegates returned to Parliament, they would speedily come to be regarded as intolerable bores. They would thus do the cause which they represented the worst possible service, for the House of Commons hates nothing so much as a bore.

SOCIETY PROCEEDINGS.

NORTHWEST MEDICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, December 1, 1903.

The President, Wm. Egbert Robertson M.D., in the Chair.

Observations on the Occurrence of Nephritis in Infancy.—This was the paper read by Dr. Charles C. Baedert, in which he reviewed the work of Goulkewitch, who, in a post-mortem study of the kidneys of 200 infants, found nephritis in 23, the primary disease being pneumonia in 11, tuberculosis in 6, and enteritis in 6; Morse, who recommended the routine examination of infants' urine; Jacobi, who divided the disease in infancy into the acute, subacute and chronic forms, and considered the cause as either congestive or obstructive; Holt, and D. J. Milton Miller, who has devoted particular attention to the study of the influenzal nephritis. He recommended that the urine be examined for albumin in all doubtful cases, as many of the fatal cases of uremia are frequently unaccompanied by edema or dropsy. Among the causes of uremia were mentioned, scarlatina, diphtheria, measles, rubella, varicella, vaccinia, malaria, typhoid cerebrospinal fevers, tonsillitis, parotitis and pyemia, whooping cough, bronchopneumonia and the stasis dependent upon other pulmonary and cardiac affections. The primary form is very rare in infants. While albumin and hyaline casts are frequently present in the urine of infants, yet after the first week they should be given the same significance as in later life. He reported four cases, all following pneumonia, which, in two cases, was a sequel of whooping cough, in one it was a sequel of influenza and in the other a sequel of acute gastro-enteritis. The first cases occurred in a child aged five months; at the beginning of the attack, there was a temperature of 103° F.; pulse 125, and some vomiting and diarrhea, from which it recovered to a great extent in three or four days, but had a cough. Twelve days after the beginning of the first attack he was again seized with fever, temperature 104° F., cough and diarrhea and on the following day had two slight convulsions. Nine days later the physical signs of bronchopneumonia appeared, with a temperature of 104.4° F.; respirations 80, and a distinct swelling and puffiness of both feet. After this the temperature and pulse continued high, and the urine showed albumin and hyaline and granular casts and pus, the child dying on the thirtieth day, after the beginning of the first attack, after having had several hard convulsions, probably uremic. The second case was a male, four months old, and was first seen in the second week of the convulsive stage of whooping cough, with a temperature of 103.2° F.; pulse 130, and respirations 50. During the course of the disease, he had been crying and fretting with spasmodic coughing, followed by vomiting. After four days he developed symptoms of bronchopneumonia, and the urine was scanty, but showed only a slight trace of albumin and no casts. He apparently improved and had a subnormal temperature for ten or twelve days, when a relapse occurred, with a temperature of 103.2°, with a return of the symptoms of bronchopneumonia, with albuminuria and numerous hyaline and granular casts and pus cells. The patient was markedly anemic and continued to grow worse until the fifty-third day of the disease, when he died. The third case was a female infant, seven months old, who was first seen with a temperature of 104° F., and a pulse of 150, and marked catarrhal symptoms indicating influenza, with moist râles, but no consolidation. Four days later bronchial breathing developed and patient continued in about same state for about a week more, when the bronchopneumonia symptoms still persisted, the patient was very pale, passed very little urine and a week later, albuminuria was present, but no distinct casts; convulsions developed in the meantime and the patient died four days later, on the twenty-fifth day of her illness. The autopsy showed areas of consolidation in both lungs posteriorly, congested spleen, enlarged and congested liver and red and congested kidneys. The fourth case was a male infant, aged four months, the illness beginning with high fever, diarrhea and vomiting, followed by extreme weakness and emaciation, and then improvement for a few days, after which he was taken with a high fever and cough, with albuminuria, pus and granular casts, followed by convulsions and death. In conclusion the author emphasized the importance of (1) the examination of the urine in all acute diseases of infancy and especially in the bronchopneumonia; (2) the importance of marked anemia as the most pronounced symptoms of kidney involvement; (3) that edema when present is a valuable symptom, but grave kidney involvement may exist without it; (4) there is almost always a diminution in the renal secretion; (5) the presence of grave nervous phenomena and convulsions.

Importance of Dropsy as a Symptom.—This was the title of the paper read by Dr. A. C. Morgan, in which he divided the condition into the unilateral, in which the cause exists in the immediate proximity; bilateral, which may be caused by obstruction of a corresponding point of the two sides affected; and the bilateral edema in which there is a central cause. The local variety is caused by pressure on the capillaries, veins or lymph spaces, and may be either acute, as from an abscess, in which it is caused by arterial dilatation; or chronic, as from lymphangitis, after operations or fractures of the bones. An important point is the association of edema of the ankles with anemia, accompanied by a slight irregular fever, oftentimes closely simulating the fever of incipient phthisis. The malleolar dropsy in anemia is chiefly due to the decrease in the solid contents of the blood caused by the primary disease, such as Bright's disease, pernicious anemia, intestinal toxemia, chronic dysentery, scurvy or cachexia. In a transudate, the skin is cold, symmetrically swollen, pale, shiny and smooth, pitting on pressure, and slowly resuming its former shape. In an exudate the skin is hot, non-symmetrical, red, pitting on pressure, constantly painful—throbbing in character, the exudate being constantly mixed with blood and breaks only when the abscess points. Edema of the skin in contradistinction to a bulging indicates that the fluid contents are septic. He stated that dropsy should always be considered as a pathological condition, requiring for its cure proper medical or surgical attention, and should be given full importance in both, diagnosis, prognosis and treatment. He stated that, as a general rule, initial dropsy of Bright's disease appears as edema under the lower eyelids, seen upon arising in the morning, disappearing by night; in valvular heart disease,

myocarditis, lung or blood conditions, its first appearance is in the ankles, appearing late in the day and increasing toward night; and hydroperitoneum or ascites is the first dropsy due to failure of compensation in the portal circulation, as in cirrhosis of the liver.

Non-Medicinal Treatment of Dropsy.—This was read by Dr. Albert G. Miller, in which he stated that there were frequently cases of edema due to cardiac or renal causes, which baffled the practitioner, if he relied upon drugs alone. Hygienic and dietetic measures should be resorted to, mental excitement avoided, as this will tend to functional cardiac derangement. The diet should be simple and the quantity limited; foods tending to produce gaseous distention or fermentation should be avoided, and if of nephritic origin the proteids should be reduced to a minimum. Water may be more limited in the cardiac than in the renal cases. The clothing should be carefully regulated, woolen undergarments being preferable throughout the year. Climatic surroundings should be carefully considered, prolonged residence in a warm, dry climate being often beneficial to the nephritic cases. Careful attention should be given to bathing—hot baths being favorable in renal, but not in cardiac cases; muscular strain and fatigue should be avoided and in severe cases, cessation of labor is desirable. Carefully regulated exercise and elevation of the part are also of value, and where there is no inflammation of the affected part, massage and electricity are of value. In some cases the use of kaolin spread thickly on the parts; and in nephritic cases, particularly if there be urinary suppression, the use of dry cups is of value. In severe cases, the employment of Southey's tubes; and in some cases accompanied by extreme cyanosis, bleeding to relieve the intracardial pressure, may be resorted to, either directly by opening a vein or by means of leeches and wet cups. In cases of transudation into the serous cavities paracentesis may be necessary.

Dr. Harry Lowenburg, in the discussion, emphasized the importance of the examination of the urine of infants as a routine measure, particularly those suffering from the infectious fevers, more especially scarlet fever, which he believed could be classified into the postscarlatinal and the septic nephritis. He believed that in nearly all cases of scarlet fever albuminuria was present at some period of the condition, and that if the skin is kept active by baths and alkaline, and fruit juices are given the patients to drink, the danger from nephritis will be reduced to a minimum. He reported the case of a colored boy whose only symptoms manifesting themselves were watering of the eyes and sneezing, the case having been diagnosed as one of hay fever. Urinary examination was suggested by slight puffiness under the eye, and there was also cardiac hypertrophy, displacement of the apex beat, and thickened arteries.

Dr. Hugh Hanna remarked the importance of early diagnosis and treatment of the nephritic condition, and reported the case of a mild scarlatinous condition, which was improving very nicely, when the patient, in the absence of the nurse, went to the window and from the effects of the cold air immediately developed nephritis, with almost complete suppression of urine for nearly forty-eight hours. By the use of actively eliminative preparations and large amounts of water the patient made a good recovery.

Dr. Luther C. Peter suggested the practicability of the employment of Fuller's earth or chalk with glycerin and some of the volatile oils.

Dr. H. C. Masland believed that the condition of the kidneys should be carefully watched throughout the course of all infectious diseases, and careful attention to any symptom arising he believed would oftentimes prevent permanent impairment or fatal results.

Dr. I. Valentine Levi reported three cases of scarlet fever in which examinations of the urine were made every other day, and no albumin was discovered, although casts were present in one, which he felt indicated the necessity of centrifugation and microscopical examination in all cases.

Dr. Arthur P. Hitchens reported that staphylococcus could be recovered from the kidneys of rabbits after five or six days, even although not strong enough to produce death, and the germs are more numerous in the kidneys than in any part of the body. With streptococcus, the reverse is true; they are practically never found in the kidneys unless the rabbit dies, and even then are much less numerous than in other parts of the bodies.

Dr. J. Thompson Schell stated that he had great difficulty in collecting the urine of infants for examination. He believed that infantile nephritis was a very frequent condition, and also that children were oftentimes born with a form of nephritis. He also felt that many cases of young infants were treated for ordinary colic when it was really of nephritic origin.

Dr. William L. Pepper reported a case of nephritic dropsy, which terminated favorably, in which the albuminuria was not increased by giving the patient a large amount of eggs.

Dr. Wm. Egbert Robertson felt that in many cases the term nephritic was a misnomer, as probably a majority of the cases of so-called nephritis, particularly all those accompanying infectious diseases, were cases of toxic degeneration. He thought that the urine from a male baby comparatively easy of collection by the use of a small bag such as is sometimes worn by adults in cases of urinary incontinence. He stated that the youngest case of this condition he had ever seen occurred in a male infant six weeks old, following an enteritis. There was anemia, but no edema, albumin, leucin and tyrosin were present in the urine. Autopsy revealed a septic infarct in the lung, from which area and the heart blood streptococcus was recovered. He divided the condition into the infectious and the metabolic, which may be due to altered metabolism, which may be due to external agencies, such as lead and other metallic poisons or to syphilis, gout and possibly rheumatism. He recommended careful examination of the urine, both for albumin and microscopically for casts in all cases of infectious diseases. Dropsy due to renal conditions, he stated, did not terminate fatally nearly so quickly as that due to cardiac disturbance, and as in renal conditions, there is usually an associated heart lesion, he felt there was a possibility of increasing the cardiac hypertrophy by the too free administration of water in the renal cases.

Dr. Ellis E. W. Given stated that at the Children's Hospital a wide-mouthed bottle was employed for the collection of urine from the male infants, and the child kept as quiet as possible, but that for female infants, the only means that could be employed was a catheter (which it was very difficult to obtain small enough), or absorbent cotton.

Dr. A. C. Morgan, in closing, stated the best method of collecting the urine was to excite urination by putting a grain or two of salt upon the lips of the meatus, or if the child is old enough, to be responsive to stimuli, running water excites urination, and then you can collect the urine in a vessel. He further stated that he had seen one case of edema of the chest wall, occurring in a woman at Blockley, the process having been present for over a year.

Dr. A. G. Miller, in closing, stated that the effect of the kaolin is due entirely to the abstraction of fluid or some toxic principle, and the remedy requires great nicety of preparation, as if too much glycerin is used,

it will not stay on well, and if too much clay is employed, it will be too hard to produce any effect.

Dr. Charles C. Biedert, in closing, stated that he saw no objection to the employment of the catheter in female infants, having used it with no untoward results. In none of the cases reported was the albumin sufficient to estimate quantitatively, and in all hyaline and granular casts and some kidney cells were present.

BOOK REVIEWS.

The Medical Record Visiting List or Physician's Diary for 1904. New revised edition. William Wood & Co, New York.

This new edition has been revised and improved in many ways. The amount of matter bearing upon emergencies of all kinds has been increased and questions of dosage and the like, particularly of some of the older drugs, have been eliminated. A welcome addition is the introduction of both the English and French systems. The hints on the writing of wills by a member of the New York bar may save many practitioners from unwelcome legal complications. The List is attractively bound in black leather and is in every way highly creditable to the house which furnishes it.

Social Diseases and Marriage—Social Prophylaxis. By Prince A. Morrow, A.M., M.D. Lea Brothers & Co., New York and Philadelphia.

Ample justification for the appearance of this work is furnished by the author in the preface, wherein he states: "There is no comprehensive treatise in our language upon this subject."

A portion of the field had been already covered by Dr. Morrow's translation of Fournier's classical monograph upon Syphilis and Marriage, yet an equally important portion has never taken definite shape in a formal treatise—namely, the relation that gonorrhea holds to matrimony, a field fully covered by the present volume.

Dr. Morrow clothes his ideas in language that flows gracefully from a willing pen; words that, at times, become crystallized into a form akin to epigram—"The present of syphilis is never the mirror of the future"—and make very agreeable reading.

This ease of diction gives the book almost a popular character.

Its line of argument could be as easily followed by the layman as by the physician, and the facts presented would be a potent incentive to a correct course of life if laid, even in their present form, before any self-respecting young man.

Moreover, the whole tone of the book is stamped with honesty. It becomes sometimes almost an appeal, glowing with the warmth of personal conviction fortified by knowledge.

The four pages upon the Causes of Prostitution (320 *et seq.*) are peculiarly forceful and bristle with suggestion.

The word-painting, always vivid, is at times impressionistic, never lurid, never gruesome.

Chapter XXX is rather a dramatic presentation of the dangers introduced by syphilis into marriage, but for that reason the more graphic.

To Gonorrhea is given about one-quarter of the text; and its relation to marriage is followed up through the possible sterility it may impose upon both sexes through the distortions of gonorrheal rheumatism, the ophthalmia neonatorum and vulvovaginitis of the young, the possible blindness at any time of life, to the final tubal, peritoneal and septic complications of the innocent victim.

Syphilis, in like manner, is carried through its relations to the individual into the parasyphilitic and late dystrophial terminations.

The medical secret is discussed in a spirit of cautious protest, and, in the way of prophylaxis, a broader education of the young is advocated as the most potent factor.

Excellent chapter heads and a full index facilitate reference. E. L. Keyes.

The Practical Application of the Roentgen Rays in Therapeutics and Diagnosis. By Wm. A. Pusey, A.M., M.D., Professor of Dermatology in the University of Illinois; Member of the American Dermatological Association; and Eugene W. Caldwell, B.S., Director of the Edward N. Gibbs X-Ray Laboratory, University and Bellevue Hospital Medical College, New York; Member of the Roentgen Society of London. W. B. Saunders & Co., New York, Philadelphia and London.

Somewhat more than a third of the present volume is devoted to a discussion of the apparatus used in X-ray work and the various technical methods involved in its application to diagnosis and treatment. The second larger part of the book is the work of the senior author, and summarizes the present status of our knowledge in regard to the therapeutics of this new agent, together with a report of cases from his own experience.

With such a variety of types of apparatus on the market it is of the greatest value to anyone contemplating an excursion into this fascinating realm of clinical physics to have their underlying principles, and consequently, fields of usefulness so clearly indicated as in the first part of this book. Each element in the make-up of the X-ray outfit is described and the fitness of the different varieties of each for special purposes pointed out. Directions as explicit as is possible in an art which, like all arts, is mainly dominated by rule of thumb precepts, are given and many ingenious and effective devices, the product of the author's experience, described. Among these are special types of tubes for use in making therapeutic applications of the rays to various cavities of the body, apparatus for localizing foreign bodies and for making stereoscopic radiographs, a special electrolytic interrupter, a clever system of filing negatives, a dark lantern, a screen for viewing negatives, etc.

The second part contains chapters on the effects of the Roentgen ray in healthy and diseased tissues, the philosophy of its remedial action in certain diseases, the technic of its application and very numerous case histories. The value of X-ray therapy in hypertrichosis, acne and sycosis is said to be above question. In triea tonsurans and favus its use is less well established, but is worthy of persistent trial, while in certain forms of eczema, lichen planus and psoriasis it has a distinct field of usefulness. Lupus erythematosus is yet unconquered, but lupus vulgaris has succumbed to the new treatment. In regard to malignant disease the author takes the optimistic ground usual to dermatologists and ascribes most brilliant results to the method. Cases in which it is particularly useful are inoperable cases, those where much tissue cannot be sacrificed, and as a temporary measure to prevent spread of the disease in cases where operation cannot immediately be performed. This section is most valuable and interesting, though its attractiveness is marred by the author's careless literary form.

A number of excellent plates and many illustrations in the text, together with beautiful presswork, contribute much to the interest of the volume.

ORIGINAL ARTICLES.

INTERSCAPULOTHORACIC AMPUTATION FOR SARCOMA.

BY CHARLES A. POWERS, M.D.,
OF DENVER, COL.:
SURGEON TO ST. LUKE'S HOSPITAL AND TO THE DENVER CITY HOSPITAL.

THE patient, Mr. H., a man of fifty-six years, is without alcoholic history; he has always been in fairly good general health. In September, 1902, he fractured the upper part of the left humerus, being treated by a competent physician with an excellent result. In December, 1902, he noticed a small lump at about the seat of fracture anteriorly. This gave him no special trouble at the time, but in February, 1893, it began to grow and a few weeks afterward he consulted Dr. S. B. Childs who made a diagnosis of sarcoma. A small piece of the growth was removed, examined microscopically, pronounced sarcoma and amputation at shoulder-joint advised. This, however, the man refused and demanded X-ray treatment, which was given by Dr. Childs until the latter part of May, the growth tending to increase. Through the courtesy of Dr. Childs I saw him about April 25. At that time there was a diffuse, semi-fluctuating growth at the upper part of the arm, chiefly in front. This was somewhat larger than a fist and seemed to be attached to the bone. Amputation again advised and refused. I next saw him May 29; the growth was much larger; it was more fusiform, extending well on the chest anteriorly and occupying the entire outer and anterior deltoid region. It seemed to be attached to the humerus but the whole mass was movable on the chest wall.

The tumor was growing, the pain was getting to be pretty severe. In spite of the fact that the urine showed a large amount of albumin (3 per cent.), I was inclined to recommend an interscapulothoracic amputation as a palliative measure and the patient requested this after its dangers had been fully set before him. Four days were devoted to improving the general condition.

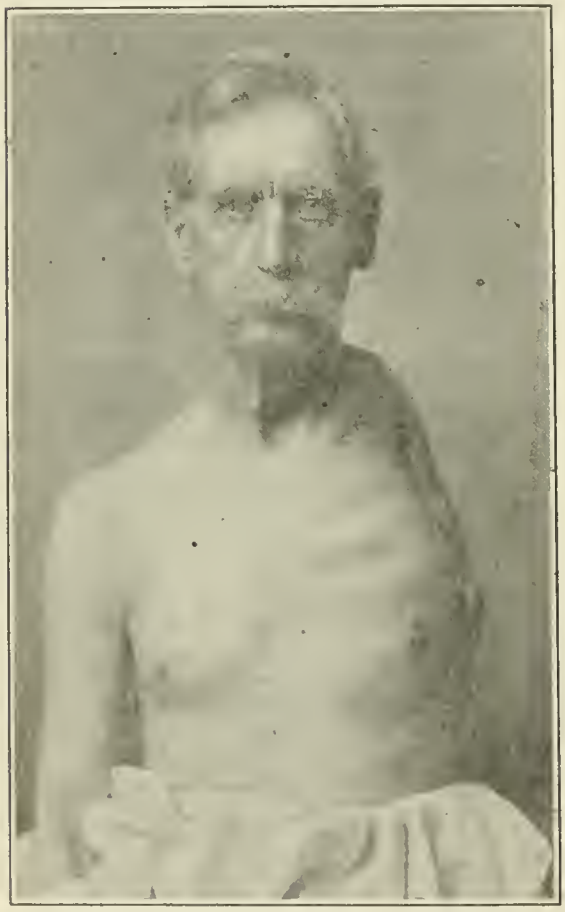
Operation.—St. Luke's Hospital, 11:30 A.M., June 3, 1903. Chloroform carefully administered by Dr. Olmstead. The middle half of the collar-bone was easily resected, the inner division being made by a wire saw, the outer division by a heavy bone forceps. The pectoralis major was divided downward about the middle of the incision giving easy access to the large vessels. Two arteries of medium size running parallel with the collar-bone were divided and tied. Directly beneath the collar-bone and with no appreciable fibers of the subclavius muscle intervening was a medium-sized vein running transversely. This was not very large and from its superficial position I at the time judged it a transverse cervical vein. It was divided between two ligatures. It proved to be the subclavian vein for directly behind it the subclavian artery was easily recognized, brought up from its sheath and ligated with heavy silk. Two ligatures a quarter of an inch apart were placed on the proximal side, one ligature on the distal side and the artery divided one-fourth inch outside of the external proximal ligature. An anterior flap was then rapidly fashioned, cutting well outside of the growth. This necessitated incision pretty well forward and inward on the chest wall. A few veins had to be caught; but little blood was lost. Abduction of the limb then put the cords of the brachial plexus on the stretch. Each cord was injected with ten minims of a one-fourth of one per cent. solution of cocaine and at the end of two minutes the cords were divided. The pulse was noted at the time of division of the cords; it did not change. As the growth was lodged in chief part anterior and external to the shoulder an unusually large posterior flap was fashioned, this connecting with the anterior flap just below the axilla. A transverse posterior cut was made just below the spine of the scapula nearly to its posterior border and the soft parts dissected up from the scapula above and below the spine. The scapula was then easily removed and the limb severed. The posterior incisions were nearly bloodless; no artery and but few veins required ligation. The flaps were brought together with moderate tension at the middle of the wound. Gauze drainage at the lower angle. Copious dressings evenly and firmly applied. Time of operation fifty-seven minutes. The patient was in fairly good condition at the close, the pulse being 130. The pulse before operation was 80, during ligation of the subclavian vessels it was 50. The patient rallied well; twenty-four hours later the pulse was 96; he had suffered but little and was very comfortable. At this time urine was being secreted freely, its specific gravity was 1.024 and it showed but a slight amount of albumin.

The gauze drain was taken out at the end of twenty-four hours. The stitches were removed on the seventh day. The wound healed throughout by first intention. The patient had at no time enough pain to require an opiate. He was out of bed on the tenth day. After operation he had X-ray treatment. The accompanying pictures show the condition at the end of two and one-half weeks. He has never complained of a feeling of lopsidedness.

During his stay in the hospital the albumin practically disappeared from the urine. No casts were found at any time. At this time, four months after operation, there is no evidence of

relapse but as histological examination of the growth showed it to be a round-celled sarcoma there is pretty sure to be a return.* The patient weighs eight pounds more now than he did before the limb was removed. Dr. J. A. Wilder, pathologist to the hospital, reports as follows on the specimen: "The external appearance of the tumor of shoulder presented for examination is that of a large, rounded, smooth mass, occupying the entire deltoid region and being 16½ inches in circumference. On section this is light flesh colored, lobulated and very friable. It is firmly

Fig. 1.



Interscapulothoracic amputation for sarcoma. Condition at end of two weeks.

attached to the sheaths of muscles and tendons in this locality and more firmly attached to and apparently springing from the periosteum at the point of a fracture of the surgical neck of the humerus. The growth appears to be partially encapsulated in places but has infiltrated in all directions. The growth macroscopically was well included within the lines of incision.

Pieces were taken from different parts of the tumor for examination, hardened in alcohol and imbedded in celloidin. Sections taken from different places stained with hematoxylin have the same general appearance: namely, a dense mass of small, round cells having large, deeply stained nuclei. A few trabeculæ of edematous connecting tissue are seen scattered through the sections. Blood vessels are present in moderate number and invariably have very poorly developed walls, many of them apparently having nothing but the endothelial lining. Diagnosis; small, round-cell sarcoma."

The question of pathological fracture following sarcoma is an interesting one. In January, 1890, I presented* a specimen of angiosarcoma of the shoulder-joint with fracture through the surgical neck of the humerus at a meeting of the Section on Surgery of the New York Academy of Medicine. This patient had fallen on the shoulder ten weeks before operation, there having been no indication of shoulder trouble previous to the injury. I saw him two weeks after he was hurt and at that time made a diagnosis of fracture, as above noted. There was considerable swelling of the shoulder-joint which became even greater after the application of a plaster-of-Paris splint. Four or five weeks later, the swelling continuing, he was sent from the out-patient department of the hospital into the hospital proper for ward treatment. The condition progressing, amputation was made at the shoulder-joint, the pathologist reporting typical angiosarcoma.

In this case my first thought was that the fracture occurred at the time of the fall and that the sarcoma was occasioned by and followed the fracture. Dr. Weir and Dr. Jacobi, however, believed in the reverse order and attributed the fracture to softening of the bone by the neoplasm. I am convinced that they were right. In the case which I am now reporting, I believe an original fracture to have united, a sarcoma to have developed and a pathological fracture to have followed. I did not know of the last fracture until examination was made of the specimen. It is possible that it took place while the arm was being manipulated during amputation.

This was my first experience with this operation and I beg to acknowledge my indebtedness to recent articles by LeConte† and Lund‡ for valuable assistance. The patient was thin and therefore ligation of the subclavian vessels was comparatively easy, but the operation itself was a little more difficult than usual because of the anterior location of the growth. Resection of the collar-bone was rapidly and easily carried out. Downward division of the pectoralis major as suggested by Lund was of marked help. I was not prepared to find the subclavian vein so closely in contact with the collar-bone. There was practically no subclavius muscle and the vein was so moderate in size that I tied it, in the thought that it was something anterior to the large vessels. In this operation one should ligate

* January 10, 1904. On correcting the proof of this MS. I receive report of the recent death of this patient from metastatic sarcoma of the hip.—C. A. P.

the artery first, elevating the limb to allow the blood in it to get back into the body, and then tie the vein. In another case I should be more careful to do this; in this instance, however, the fact that the vein was first ligated does not seem to have prejudiced the result. After ligation of the subclavian vessels the operation was practically bloodless and was very easy.

The operation is one requiring good light, suitable position of the patient and proper hospital organization. The best position is at the edge of a flat table with a small sandbag between the shoulders.

Fig. 2.

Interscapulothoracic amputation for sarcoma. Condition at end of two weeks.

Tinker* attributes the first operation of this nature to Dixi Crosby, of Hanover, N. H., in 1836. The subject has recently been studied with much care by LeConte (*loc. supra cit.*). The key to the procedure lies (Berger) in primary ligation of the subclavian artery and vein. For the rapid and easy carrying out of this I judge such resection of the collar-bone as was made in my case to be fairly suitable. When the collar-bone itself is involved in the new growth disarticulation of its sternal end with reflection outward of the entire bone must be done as advised by LeConte; it may be that this procedure will prove to be the easier and more rapid in all cases. After removal of the collar-bone, division downward of the upper part of the pectoralis major with section of the pectoralis minor as advised by Lund will be found of marked benefit. Unless the patient be pretty fat and the wound deep, access to the subclavian vessels will then be fairly easy; there may, however, be very large veins in front of these vessels and LeConte shows that various operators have experienced considerable difficulty not only with venous hemorrhage but in recognizing the vessels themselves or in gaining access to the artery. An experience of but one case does not warrant an opinion, but it seems to me that in a difficult case I would rather tie and divide all veins as rapidly as possible down to the artery than consume a great deal of time and risk injury to the veins in an endeavor to get the artery first. In such cases LeConte advises primary ligation of the axillary artery, working back from this point to the third part of the subclavian. If one wounds a good-sized vein in this region he is bound to have some difficulty in securing it and his patient is pretty sure to lose a fair amount of blood.

After ligation of the vessels the operation is easy and can be completed rapidly. The flaps will be fashioned according to the location of good tissue. The researches of Crile seem to show that cocainization of large nerve trunks should be made before their division. Lund lays stress on this. It takes but little time and seems worth doing. In the case here reported the pulse showed no change when the cords of the brachial plexus were divided.

Berger,* who with Farabeuf developed the modern technic thinks the operation attended with but moderate risk unless malignant disease involves the scapula. In these cases a large amount of tissue overlying the shoulder blade must be removed, the resulting wound is difficult to close and the mortality goes fairly high. Barling, quoted by Jacobson and Steward,† also thinks the mortality low. Of 19 cases, recorded since 1890 and collected by him, all recovered.

PREVENTION OF THE SPREAD OF RINGWORM.

BY F. H. BEADLES, M.D.,
OF RICHMOND VA.;
LECTURER ON DISEASES OF THE SKIN, MEDICAL COLLEGE OF VIRGINIA; DERMATOLOGIST TO THE FREE DISPENSARY, MEDICAL COLLEGE OF VIRGINIA.

WRITERS from the time of Celsus to the present day have endeavored to improve the nomenclature of the mycotic group. It has long been undisputed that the various lesions described under the title of ringworm are due to the presence of a vegetable parasite in the epidermis, hair follicles, hair or nails. Up to the present decade the fungi found in the various forms of ringworm were believed to be identical. More than

* Semaine Médicale, 1903.
† Operations of Surgery, Vol. i, p. 182.

fifty years ago Gruby indicated a division of the fungi causing ringworm. But his wonderful discoveries were not only not appreciated, but unrecognized, and the *Tricophyton* was accepted by most physicians as the sole factor in all ringworm cases.

Sabaraud, with the advantage of more modern training and inexhaustible patience, brought this subject to a higher plane both clinically and pathologically and established beyond question, the division of ringworm into two classes—the *Microsporon Audouini*, or small spore fungus, and the *Tricophyton*, or large spore fungus, the latter being again subdivided. He frankly admits his work to be simply an elaboration of Gruby's discoveries.

Encouraged by the brilliant results of Sabaraud and stimulated by the necessity for conquering this ever-increasing disease, hundreds of workers have begun the investigation of this subject and have made valuable additions to our knowledge of ringworm fungi.

In this paper the writer desires to point out, as briefly as possible, some of the mediums of transmission. Among these may be mentioned some of the lower animals, as the dog, cat, bird, horse, cow, mouse and sheep and many others. That domestic animals and pets are great transmitters of this disease is proven by the fact that fungi derived from animal sources, though of different species, show a greater vitality than those derived from human sources. Experience proves that the nearer a fungus is to its animal origin the more rapid its growth; also that it loses its vitality by human transmission.

Recently the writer had presented a case of body ringworm. In the house of the patient was found a mangy cat. Microscopical examination disclosed the presence of the same fungus—the *Ectothrix*—in the lesion of both the patient and the cat, thus confirming the suspicion that the disease had been contracted from the cat. Animals, however, cannot be held entirely responsible for the transmission of this disease when we consider the excellent opportunities for diffusion offered by barber shops, bath houses, asylums, day nurseries, and, last but not least, our public schools. That barber shops and hairdressing establishments play an important part in the transmission of these diseases is not to be wondered at when we remember the usual unsanitary condition of these shops of infection.

The disease is not, as is popularly supposed, conveyed by the razor, but by the barber's hands or towels and oftenest by the lathering brush Not only is the adult exposed here, but frequently the innocent child who has his hair cut brings away as a souvenir of the occasion a fine case of scalp ringworm. And now for its widest field of action. In our schools, side by side, are seated children from all kinds and conditions of homes. We are not surprised at the increase of this disease when we consider the facility of transmission of fungus either directly from child to child (through the medium of some contaminated article) and sometimes even by means of the air alone, when there are many affected children congregated. It flourishes more readily in badly nourished or uncleanly children, yet I have met extremely obstinate forms in otherwise healthy children. The gregarious habits of children, the frequent and intimate character of contact in their amusements and studies, and their indiscriminate use of hats, caps, etc., greatly increase the chances of contagion when one of their number is affected with this condition.

Our public schools require certificates of vaccination or of recovery after the acute infectious diseases, yet children affected with scalp ringworm are allowed the privilege of the school room, scattering contagion broadcast. Although its effect upon the skin is usually insignificant, its occurrence in a family or school is a real calamity, owing to its contagiousness, and the social ostracism it entails. Frequently these diseases are brought into a school and there disseminated to the extent of an epidemic, thereby seriously interfering with education. It is a common occurrence in my clinic to find cases of scalp ringworm and, upon questioning the individual, to learn that they are in attendance upon school. We, as physicians with the aid of the modern medical society can do much to correct these evils. That the number of cases of vegetable parasitic disease transmitted through our public schools is steadily increasing is proven by statistics and calls aloud for legislative restriction. Since 1844, Paris has had physicians as school inspectors and now Paris, Brussels and Rome have separate schools for children suffering with ringworm. During their residence in these schools, children receive education and treatment under the care of physicians. For fifteen years legislation through the efforts of the medical societies was sought in New York, but in vain. It was only when they entered the political field and publicly called legislators to account that they succeeded in establishing the Metropolitan Board of Health, the first of its kind (based on sound sanitary principles) in this country. Many other cities, among them Boston, Philadelphia and Chicago, have realized the enormity of this evil and have appointed school inspectors, either physicians or nurses, whose duty it is to visit the schools as frequently as possible and indicate to the teacher or principal each child affected with any contagious disease, parasitic or otherwise. All suspected cases are immediately excluded from the school until they can furnish a certificate from their attending physician stating that all danger of contagion is removed. Physicians attending such cases should withhold the certificate for several weeks after the disappearance of all diseased hairs and stumps. If the case exist in a boarding school or asylum the patient should be isolated if possible and all others who have been exposed be subjected to a thorough examination, sparing neither time nor trouble, and giving careful attention to all isolated stumps and suspicious scaly patches. The appointment of medical in-

spectors in the schools shows gratifying results, not only in the decrease of the per cent. of cases but also in the personal hygiene of the children, those who formerly came to school unclean gradually improving in their appearance and habits. Parents, to whom this disease is the scource of much anxiety, soon learn to appreciate the value of these measures and acquire a better understanding of the necessity of isolation. The writer would urge greater frankness to ourselves as well as to our patients in dealing with these diseases. The practitioner sometimes fails to appreciate the importance of detail, and carelessness in this respect is responsible for a number of cases. The physician's first duty in the management of ringworm is to prevent the spread of the disease to others. He should insist upon an examination of all other children in the family or school and, while making such examination, he should not forget that his hands, if not properly cleansed, may convey the disease to those as yet unaffected. The scalps of all the children should be thoroughly washed several times a week until all danger of contagion is past.

The individual under treatment should be required to sleep alone and use separate towels, combs and brushes, these articles being frequently sterilized to prevent reinfection. All domestic animals or pets which are found to be mangy should be either destroyed or isolated until by proper care they can be rendered incapable of the transmission of the fungus. As a rule the poorer the people the larger the number of cats and dogs they possess. The extra tax recently imposed by the legislature has done much to decrease the number of these nuisances and so lessen this means of transmission. The establishment of sanitary barber shops where brushes, razors, etc., are sterilized just before being used can do much to diminish this trouble. Persons who patronize these shops should provide their own equipment, whereby they will probably protect themselves from infection. On the other hand, infected cases should not be taken to the barber shop to have their hair trimmed or shaved, but it should be done at home and the diseased hair burned. Briefly considered, this seems a reasonable solution of this evil, and I believe we are justified in requesting the help of the law in our efforts to restrict this disease. Large expenditures are made yearly by both State and city for objects less worthy, yet little thought is given to the physical welfare of the child—the future dependence of our country. Prophylaxis has invaded the domain of nearly every disease; its science and practice are daily increasing and its field of usefulness becoming better known. Scientific research can demonstrate few more valuable triumphs than the results of preventive medicine.

Consultants to Bellevue.—At a meeting of the Trustees of Bellevue and Allied Hospitals held January 8, 1904, the following physicians were appointed Alienists and Neurologists to Bellevue Hospital: Drs. Frederick Peterson, Joseph Fraenkel, Edward D. Fisher, Bernard Sachs.

CRYOSCOPY OF URINE. THE METHOD OF CLAUDE AND BALTHAZARD.

BY F. BURTHE, M.D.,
OF PARIS, FRANCE.

THE biological applications of cryoscopy have, among other interesting results, raised up a new theory as to the renal secretion, and furnished about the disorders of this function, as well as about the general nutrition, some indications of a very high value. Without any theoretic consideration or scientific discussion on the grounds and relative weight of the various processes used by several authors in order to apply cryoscopy to the physiological studies, I only wish to state the way that Claude and Balthazard, from Paris, have pursued, and the results at which they have arrived.

It is necessary to accurately collect the urine which was passed during twenty-four consecutive hours, so as to get an average urine from which the freezing point can be taken. This freezing point is found, in practice, to vary between—1° 30 C. and —2° 20 C. Claude and Balthazard name it J and express it by hundredths of a degree C., stating that the number so obtained represents the number of solid molecules dissolved in 1 c.c. of urine. That statement is perfectly allowable, as, according to de Coppet's law "the fall of the freezing point of a dissolution is proportional to the number of solid molecules contained in a given volume of this dissolution," so that if $J = -1°.30$ C., then there are a number of solid molecules proportional to 1.30, or more simply to 130, in 1 c.c. Now if V expresses in "centimeters cubes" the volume of urine that is passed during twenty-four hours, then the product $J V$ may represent the number of molecules eliminated with the urine of the day; and, in order to get some comparable results from the different subjects, one must refer to the unit usually chosen as characteristic of the living matter, that is to the kilogram of the body's weight. So that if P is the weight of a subject, one must divide by P the already obtained product $J V$, and then one will have a number $\frac{J V}{P}$ which expresses what Claude and Balthazard have named "the total molecular diuresis." This total molecular diuresis represents as well the number of molecules that have filtered through the glomeruli during the last twenty-four hours and for each kilogram of the body's weight. While in normal state this number varies from 2,500 to 4,000.

Tabling off from that total number of the excreted molecules, the number of the molecules of chloride of sodium, one will have a right to say that only elaborated molecules are left remaining. Accordingly the amount of chloride of sodium ($NaCl$) must be ascertained with great precision and in that process is obtained a number, p grams per cent., *e.g.*, for the use of which it is allowable to say that, in compliance with Blagden's law, as —0° 605 C., is the freezing point of a dissolution of $NaCl$ at 1 per cent., that salt

causes a fall of the freezing point of the urine, of p x 0.605, or, as before, there are in the urine p x 60.5 molecules of NaCl for 1 c.c. So that there are p x 60.5 x V molecules of NaCl excreted during the twenty-four hours and $\frac{p \times 60.5 \times V}{P}$ for each kilogram of the body's weight, number that we should have to take from $\frac{\Delta V}{P}$ in order to get the new number $\frac{\delta V}{P}$ named by Claude and Balthazard as "the diuresis of the elaborated molecules."

In good health that number varies according to the diet, the exercise and the activity of the nutrition, but it oscillates between 1,800 and 2,500.

We are now in possession of two valuable means of investigation about the renal secretion, as $\frac{\Delta V}{P}$ gives some information as to the number of molecules that have filtered through the glomeruli and consequently must vary in the same way as the activity of the circulation in the kidneys; while $\frac{\delta V}{P}$ points out the way which works the epithelium of the tubulis and so gives a measure of the urinary depuration.

To these two numbers Claude and Balthazard have joined a third one, $\frac{\Delta}{\delta}$ expressing the relation between the number of molecules that have filtered through the glomeruli and the number of elaborated molecules that have been excreted; that is to say, that $\frac{\Delta}{\delta}$ measures the rate of the molecular exchanges.

Between the three numbers there are necessarily some relations which in order to discover, Claude and Balthazard have studied a great many normal urines, by means of which they have been able to frame some scales of correspondence, enabling anyone to graphically represent the results of the study of any urine. According to these authors, the scale of

$\frac{\Delta V}{P}$ beginning at 0 progressively increases by 500

$\frac{\delta V}{P}$ " " 0 " " 300

$\frac{\Delta}{\delta}$ " " 1 " " 0.10

as may be seen in the following table, which shows what amount $\frac{\Delta}{\delta}$ must not exceed for each value of $\frac{\Delta V}{P}$ if the kidneys are sound.

$\frac{\Delta V}{P}$	$\frac{\delta V}{P}$	$\frac{\Delta}{\delta}$
3,000	1,800	1.60
2,500	1,500	1.50
2,000	1,200	1.40
1,500	900	1.30
1,000	600	1.20
500	300	1.10
0	0	1

The reader will note, and we beg leave to insist upon this remark, that, until now, there is nothing hypothetical in all that has been said; Claude and Balthazard have only translated in forms for the use of physiologists the laws of cryoscopy just as these have been worded by their authors.

We will now examine what applications they have made of their formulæ and what interpretation they have given to their results. For this purpose they have acknowledged the theory of Koranyi, to which we have alluded in the beginning of this paper, but that theory is not indispensable, and the results at which Claude and Balthazard have arrived by their researches would exist in their integrity and strictness, even if Koranyi's theory were not admitted. The interpretation only might be slightly different, and yet this would apply to a few of these results and not to all of them.

According to Claude and Balthazard, in *cardiac insufficiency* the rate of $\frac{\Delta V}{P}$ and $\frac{\delta V}{P}$ is low, and the more so that the circulation is slower; but, kidneys being sound, the corresponding values of $\frac{\Delta}{\delta}$ are also very low down. On the contrary, in *cardiac hyperstenia* the values of $\frac{\Delta V}{P}$ become higher than 4,000.

In *renal insufficiency* $\frac{\Delta V}{P}$ is normal or low, $\frac{\delta V}{P}$ very low, but $\frac{\Delta}{\delta}$ becomes exceedingly high in reference to $\frac{\Delta V}{P}$.

Close to these standards, allowing a diagnostic not yet wholly proved, it is possible to find many other forms sometimes more difficult of interpretation. For instance, the arterial hypertension of arteriosclerosis may be characterized by some high values of $\frac{\Delta V}{P}$ with $\frac{\Delta}{\delta}$ unsettled, as there is or is not some renal insufficiency. For some cardiac patients whose kidneys were at the same time insufficient, $\frac{\Delta}{\delta}$ had some values too high for the numbers of $\frac{\Delta V}{P}$.

Claude and Balthazard, though thinking their results sufficiently plain and precise to enable them to make a diagnosis, have always endeavored to make the clinic and cryoscopic examinations run parallel, using various processes of investigation at the same time with cryoscopy, and controlling, as many times as it was possible, their diagnosis by means of pathologic anatomy and histology. They have thus been able to describe a cryoscopic standard of cardiac hyperstenia and another of renal insufficiency. In the nephritis they have seen that there are, during the course of the illness, some periods of a sufficient permeability of the kidneys, and some other periods

of insufficiency, these last becoming more and more frequently until they culminate in a terminal period of total insufficiency. As for the substances dissolved in the urine, their elimination is relatively more abundant, apart from the uremic fits, in the interstitial nephritis than in the ordinary form of chronic Bright's disease.

But the formulæ are chiefly useful because they allow us to see in Bright's disease some latent insufficiencies which need a very long time to bring about some accidents of auto-intoxication. Repeated examinations during a few consecutive days may disclose some transitory insufficiencies hardly surmised after a mere clinic examination.

In the severe infectious illnesses, which may be complicated with heart or kidney disease, it is expedient to know early what is the functional value of these organs. Claude and Balthazard have determined the cryoscopic form of the urine in some cases of diphtheria and of typhoid fever, and found it sufficiently steady to show, through a change of the ordinary relations, that the heart or the kidneys are not perfectly sound.

Very special and nearly pathognomonic is the cryoscopic form in pneumonia. At the outset the values of $\frac{\Delta V}{P}$ are normal and those of $\frac{\delta V}{P}$ are often higher than normal, while the values of $\frac{\Delta}{\delta}$ are very low and nearing the unit; which is consequent with the absence of chloride of sodium in the urine. Two days after the fall of the temperature comes on a urinary crisis, which Pick had already observed during which $\frac{\Delta V}{P}$ and $\frac{\delta V}{P}$ slightly grow, while $\frac{\Delta}{\delta}$ increases suddenly and reaches, or even passes its normal value; and there is a urinary discharge of chloride of sodium. But this discharge, far from being transient, as is generally believed, lasts two or three weeks, as a long time is required for the resorption of the overflow.

At last, in pleurisy, the cryoscopic curve of urine plainly illustrates the various stages of the overflow's evolution; the values of $\frac{\Delta}{\delta}$ remaining low during the increasing and the stationary stages, only to rise suddenly when the overflow begins to be resorbed. Koranyi had pointed out the rapid fall of the relation $\frac{\Delta}{\Delta NaCl}$ at the time of the resorption of pleural overflows; Lesné and Ravault have recently confirmed that fact. It is easily seen that the relations $\frac{\Delta}{\delta}$ and $\frac{\Delta}{\Delta NaCl}$ do vary in opposite directions, $\frac{\Delta}{\delta}$ rising and $\frac{\Delta}{\Delta NaCl}$ falling when the amount of chloride of sodium in the urine increases.

After all, if we multiply the volume V of urine that is voided during twenty-four consecutive hours by the freezing point Δ, expressed in the hundredth of a degree C. of this urine, and divide the product by the weight P of the body, we get a value $\frac{\Delta V}{P}$, which represents the molecular elimination for the twenty-four hours and for each kilogram of the body's weight; while the elimination of the non-chlorined substances coming from the disassimilation is expressed by the formula $\frac{\delta V}{P}$. These two values may diminish and reach some very low values in cardiac insufficiency and in the renal impermeability too; this first result is beyond dispute and through it, the cryoscopy, is a way to appreciate scientifically and very quickly any urinary elimination.

Moreover, Claude and Balthazard have seen that the ratio $\frac{\Delta}{\delta}$ compared with $\frac{\Delta V}{P}$ may have a diagnostic significance and characterize the alterations of the renal epithelium. The relations between $\frac{\Delta V}{P}$ and $\frac{\delta V}{P}$ which express this renal insufficiency, have been empirically fixed by means of observation and anatomoclinical studies of a great many cases. The scheme of renal impermeability so found has always been conformable to the facts.

These results are easily interpreted by means of the Koranyi theory as to the renal secretion, which is corroborated by a certain number of physiological facts. Koranyi asserts that through the glomeruli filters a pure or nearly pure solution of chloride of sodium, which concentrates while in the tubules by some resorption of its water, and is enriched with the extractive matters from the blood by means of molecular interchange, so that for each molecule coming from the blood to the urine, one molecule of chloride of sodium passes from the tubules to the blood, and the secretion of elaborated substances is the result of the activity of the epithelial cells of the tubulis contortis. When this epithelium is injured, the interchange is, of course, less perfect and there is an excessive quantity of NaCl excreted; and then the value of δ becoming more and more different from the value of Δ the ratio $\frac{\Delta}{\delta}$ will be greater and reach, for a given value of $\frac{\Delta V}{P}$ some values higher than those which occur when the kidneys are sound. On the other hand, if there is a mere interchange of molecules in the tubules, the number of molecules that have filtered through the glomeruli is the same as the one $\frac{\Delta V}{P}$ found in the urine and this number of molecules being proportional to the rate of the circulation in the capillaries of the glomeruli the conclusion must be that $\frac{\Delta V}{P}$ is a measure of the circulation's activity.

Some authors have written that the Claude and Balthazard method was grounded on a far from

being demonstrated hypothesis. From what precedes it is easy to infer that it would be fairer to say that this method has its ground on facts, and that the interpretation of those facts only wants Koranyi's hypothesis. That interpretation, after all, is not necessary, the method, just as it is, has already given to its authors and several other observers, some results worth notice and in perfect compliance with the other means of exploring the renal function.

THE PATHOLOGY AND TREATMENT OF OSTEO-ARTHRITIS.

BY EDWARD M. MERRINS, M.D.,
OF NEW YORK.

In a recent paper on the relation of articular rheumatism to other arthritic affections, the Russian writer Predtetschensky enumerates no less than sixteen varieties of joint disease, and doubtless the possibility of further differentiation has not been exhausted by him. With all deference it must be objected that such elaborate classification is not greatly to be desired. Effort should rather be made toward simplicity and unification. Thus all forms of joint disease which occur during the course of, or as the sequel to, the infectious or toxic diseases might well be collectively known as "infective" or "toxic" arthritis. Individually, such cases, by the adjectival use of the name of the primary disease in designating them, should remain linked with that disease, regardless of the extent and duration of the morbid process in the joint. This group, containing as it does both rheumatism and gout, is clinically very large, and in strictness should include many cases of chronic joint disease which at present are not within it.

With the exception of the cases due to simple traumatism, the remaining arthritic affections are swept together for the most part into the class called "Rheumatoid," and, consequently, it is in this heterogeneous collection that we find the most profuse and bewildering assortment of titles. "The domain of progressive deforming polyarthritis," writes Predtetschensky,[1] "will contain besides the essential polyarthritis deformans, and malum coxæ senilis, the varieties which have been known as polyarthritis chronica villosa hyperplastica, many cases of nodular rheumatism, and some of Heberden's nodules; others will be found to belong in the class of uric polyarthritis," and so on. It will be a decided gain if these and other irregular joint affections can be made to fall naturally into two or three well-defined groups.

In a previous paper[2] the writer has dealt with "Rheumatoid Arthritis," which is regarded as a distinct constitutional disease, usually if not always of toxic origin. Beginning with inflammation of the synovial membrane, eventually all the arthritic tissues are implicated in a morbid process essentially atrophic, and the joint becomes constricted, deformed, limited in its movements, and, in extreme cases, anchylosed. Muscular wasting and shortening conduce greatly to this result. The general symptoms are irregular fever, anemia, emaciation, pain, muscular twitchings and cramps, disturbed reflexes and other evidences of a constitutional polyarticular disease in which the nervous system is more or less deranged.

Osteo-arthritic affections constitute the other main division of the rheumatoid group. In osteo-arthritis, which may be either non-articular or polyarticular, the brunt of the disease falls upon the cartilages and articular ends of bones, not upon the synovial membrane as in rheumatoid arthritis. The changes in the affected joints are partly destructive and partly hypertrophic. As a rule the cartilage is the first to suffer. It becomes fibrillated and eroded, especially where it is subjected to pressure and friction. At the margin of the articulation where the morbid process is less intense and the proliferating cells are prevented from escaping by the overlapping synovial membrane, the cartilage hypertrophies and becomes heaped up in irregular nodules or ecchondroses, which give a lipped appearance to the articular borders. Subsequently these nodules undergo calcification or ossification; sometimes they break off and form "loose bodies" in the joints. The same double process of destruction and overgrowth takes place in the ends of the bones. Subjected to pressure and friction, they become flattened, worn away or absorbed, but in the parts free from mechanical influences, there is hyperplasia, ending in the formation of osteophytes and other bony enlargements. The synovial membrane is also affected;

it becomes thickened, indurated and its fringes hypertrophied, and in the latter stages of the disease may be destroyed by ulceration and absorption.

Ligaments and adjacent tendons undergo calcification or absorption. The whole articulation may thus become quite altered in its form, and its function almost if not quite destroyed.

This infection is seen most frequently in elderly people. It commences insidiously with weakness, stiffness and pain. The weakness is most perceptible if the affected joints are concerned in locomotion. The pain is either of a constant gnawing character, or consists of sharp needle-like thrusts. The stiffness, made worse by rest, improves or temporarily disappears during exercise. As the disease advances these symptoms become more severe; the joint begins to creak and grate on movement, its range of movement becomes mechanically limited by the presence of chondrophytes and osteophytes between and around the articular surfaces, and the muscles in the neighborhood of the joints become wasted and contracted. There may be considerable effusion into the joint. When this is absent, the affection is known as "Arthritis sicca." At no time is the general health seriously, if at all, impaired. The progress of the disease is very slow, and these patients live usually to a good old age.

The forms of osteo-arthritis which have received particular names are Heberden's nodes, spondylitis deformans, and malum coxæ senilis.

Heberden's nodes are the little bony protuberances upon the terminal phalanges often seen in old people, and, as pointed out by the writer elsewhere,[3] are to be found in such diverse conditions as gout, cancer, dilatation of the stomach, rheumatoid arthritis and syphilis.

As these nodes are simply an abnormal growth of bone, they are structurally quite different from the chalky deposits on the fingers seen in gouty cases. Their significance consists in being an early indication of a general tendency to osteo-arthritis.

Spondylitis.—The whole or part of the vertebral column may be affected by osteo-arthritis. Nodular deposits are formed at the edges of the articular cartilages which ultimately become ossified, and the contiguous ligaments and fibrous tissue are implicated in the same process. The intervertebral discs subjected to unusual pressure, become atrophied. If anchylosis occurs before this atrophy has proceeded far, there is little or no spinal curvature, but if it occurs afterward, the deformity may be considerable. The condition is then known as spondylitis deformans. In many of these cases there is a history of gonorrhea. The spine alone may be affected, but generally either the hips or the shoulders, according as to whether the cervical or lumbar region of the spine is the part diseased, are also involved. This becomes the Spondylosis rhizomeligue of Strümpell and Marie. The spinal deformity and rigidity described by Van Bechterew under the name "kyphose heredo-traumatique" appear to be simply the secondary symptoms of a chronic meningitis, the ligamentous and osseous structures of the vertebral column being unaffected.

Malum Coxæ Senilis.—Osteo-arthritis is especially apt to affect the hip-joints of elderly people, and at first it was supposed that it never manifested itself in any other way. Hence this particular name, which very properly was discarded soon after it was originated, and it ought not to be in use at the present time. In the hip the disease generally follows an injury, such as a fall upon the trochanter. Pain, difficulty in walking, or a slight limp are among the earliest symptoms.

The intrinsic pain of the joint may be elicited by pressure over the capsule and by passive movement of the limb in various directions. Usually, the patient complains far more of the referred pains. These may be very severe in the region of the external cutaneous nerve, the condition thus somewhat resembling meralgia paresthetica; or they may be referred to the knee as in tuberculous coxitis. Often the pain is that of sciatica, and unquestionably, in many instances of apparently uncomplicated sciatica, the underlying condition is that of osteo-arthritis of the hip.[4] In an article just published,[5] Bruce goes much further, the careful study of 418 cases of sciatica convincing him that this affection is simply the forerunner of osteo-arthritis, "sciatica when unrelieved, eventually terminating in rheumatoid arthritis, which in its turn leads to bony deposits on the femur, and also on the ilium, these changes again proceeding to anchylosis between the femur and the pelvis." In yet other cases, the pain is in bulk, the sufferer clasping the thigh all around and saying that pain is in every part of it.[6] This widespread distribution of pain is applicable to the fact that in a number of these cases, the lower part of the spine is osteo-arthritic as well as the hip, consequently the lumbar and sacral nerves emerging from the affected region are continually being swept by currents of pain. Muscular wasting is quite marked and the limb may be considerably shortened, especially in those cases where the neck of the femur is undergoing the rarefaction and absorption incident to old age.

Other joints apt to suffer, but which have received no particularly descriptive names, are the shoulder and the knee.

Pain, limitation of movement, creaking and grating and muscular wasting are the principal symptoms of the disease in the shoulder as elsewhere. Where the enlargement of the head of the humerus is smooth and rounded, the general aspect of the joint may for the moment mislead one into thinking a subcoracoid dislocation is present, as in addition to the symptoms of pain and restricted movement, there is a marked prominence in front of the shoulder and what seems to be a depression behind. In the shoulder

as in the hip, the disease often follows an injury, especially in the old.

The knee is the joint which is attacked most frequently. Often both knees are affected, either concurrently or consecutively. One of the earliest symptoms in these cases may be sudden, unexpected and often most embarrassing weakness of the knees, which give way completely. A patient of the writer's affected in this manner while out walking, was compelled to clutch desperately at a lamp-post to save herself from falling, and the fear that passers-by would think she was intoxicated added greatly to her distress. The creaking and grating, nodular enlargements and other evidences of the disease are similar to those in other affected joints and need no particular description.

The question now arises: Does this arthritic complex of enlargement of the ends of the bones, calcification of ligaments and destruction of cartilage and synovial membrane, occur in other diseases? It is an important question because the comparatively few cases of osteo-arthritis, now deemed idiopathic, have no characteristic symptoms, constitutional or otherwise, and if practically identical articular lesions are found in a variety of conditions, it may reasonably be assumed that osteo-arthritis is always a secondary affection. The answer must be in the affirmative, for to mention only a few diseases out of many, the morbid anatomy of the joints in such dissimilar diseases as locomotor ataxia, gout, and hemophilia is often practically the same as in osteo-arthritis.

Further, in such cases as syphilis and osteitis deformans, in which the characteristic osseous lesions occur in the shafts of the bones, not infrequently the joints also suffer and become osteo-arthritic. "At the edges of the condyle," so runs the description of a syphilitic knee-joint, "were nodular outgrowths of cartilage, such as are commonly seen in osteo-arthritis; none of them were of large size; the external condyle was lipped in a very marked manner."[7] In a case of osteitis deformans, the arthritic changes "were identical in character with those found in certain types of rheumatoid arthritis, or perhaps more correctly, osteo-arthritis."[8] Conversely, in acute articular rheumatism, the shafts of the bones may be affected as well as the joints, periosteal nodes often forming upon them, and in cases of osteo-arthritis, hypertrophy of the shafts and epiphyses has been noticed.[9] From this it may be inferred that allowance being made for the effects of articular movements, there is no essential difference between overgrowth of the shaft of a bone and overgrowth of its extremities. To ascertain precisely the nosological position of osteo-arthritis, it will be necessary therefore to collate comprehensively all the conditions in which there occur arthritic or osseous lesions more or less resembling those found in osteo-arthritis. This may conveniently be done by forming them into three divisions:

I. Infective or Toxic. II. Nutritional. III. Traumatic.—I. The characteristic lesions of osteo-arthritis may occur during the course of many infective or toxic diseases. Thus we find them in locomotor ataxia,[10] tuberculosis,[11] leprosy,[12] syphilis, gonorrhea (Rheumatisme blennorrhagique a forme nouese), rheumatism, gout, rheumatoid arthritis and in syringomyelia,[13] a disease probably of infective origin also. They are also found in cases of chronic gastro-intestinal antiintoxication particularly in the form of Heberden's nodes,[14] in uterine disease[15] and during the systemic disturbance incidental to the menopause, in chronic pulmonary affections (hypertrophic pulmonary osteo-arthropathy), and in other local conditions from which septic infection may arise. Whether the irritation inducing the arthritis in these diseases is from the irritant action of the germs themselves which have obtained access to the joints by way of the blood stream, or from the chemically irritant action of the toxins elaborated by them, is an interesting question. Poynton and Payne[16] isolated a diplococcus from the diseased knee-joint of a dead human being, and injected a culture of it intravenously into a rabbit, which in turn developed an arthritis of the knee. Ten weeks later the animal was killed and the bones of the knee-joint were found to be thickened and lipped. On the other hand it has been shown by experiment that the prolonged administration of small doses of inorganic poison is capable of inducing hyperplasia of bone. No doubt the action of toxins is the more persistent and damaging, and apparently they may remain in the system and continue to produce their harmful effects, long after the original disease has subsided and the germs have disappeared from the fluids of the joints.

Those diseases in which there is a very pronounced arthritic diathesis, as rheumatism, gout and rheumatoid arthritis are exceptionally prone to osteo-arthritis and furnish most of the polyarticular cases, it being assumed in this connection that rheumatism is an infective disease, and that the characteristic features of gout and rheumatoid arthritis are due to toxic substances present in the system. For convenience of expression, and because the writer believes that the osteo-arthritis is simply the terminal expression of the original disease, new terms are used in the description of these conditions, which it is hoped will make for clearness, and not cause confusion to be worse confounded.

a. Rheumatic Osteo-arthritis.—The term "chronic rheumatism," as commonly used, covers a multitude of joint troubles. It should strictly be limited to those cases of acute and subacute articular rheumatism in which there is never complete recovery because the rheumatic process continues to smolder on in the joints, or else the tissues of the joints have been so damaged, or their vitality so impaired, that they never return to their normal condition even though the specific rheumatic process may long ago have ceased. It is easy to understand how cold and wet and excessive use in such cases may cause a recrudes-

cence of the disease. There are several degrees of chronic rheumatism. In the mildest cases, pain and stiffness are the only symptoms, with perhaps a little synovial crackling. In others, there is thickening of the synovial membrane and capsule which eventually may contract and so cause deformity, but cartilage and bone are unaffected, the "fibrous rheumatism" of some authors. In still another group, after repeated attacks of acute or subacute articular rheumatism, lipping occurs or osteophytes are formed, the disease thus merging into osteo-arthritis.[17]

b. Gouty Osteo-arthritis.—It is a matter of common observation that osteophytic formation and the destruction of cartilage may result from repeated attacks of gout in a joint.[18] Osteo-arthritis occurs still more frequently in women who belong to gouty families, although gout itself may seldom or never attack them in its typical form.

According to the latest theory of the nature of gout, as expounded most suggestively by Woods Hutchinson,[19] the excess of uric acid in this disease is ascribed to the disintegration of those leucocytes and fixed cells of the body which have been destroyed in the process of combating or neutralizing certain toxins of gastro-intestinal origin. Uric acid is a chemical end product of the disintegration of the nuclein of these cells, and the failure of the system to eliminate it, leads to its disposition in the various tissues of the body, particularly in the joints. Another end product is phosphoric acid, and it is possible that the retention in the system of the compounds of this substance to an abnormal amount, may be one of the causes of osteophyte formation in chronic gout, for Wegner has shown that the prolonged administration of small doses of phosphorus to animals induces a very marked hyperplasia of bone. But whether the irritation causing this hyperplasia arises from the excessive phosphates in the system, or from the mechanical irritation of the crystals of sodium biurate deposited in the tissues of the joints, or from the toxins which originated the primary disease, there is undoubtedly a very close connection between chronic gout and osteo-arthritis, as shown by the frequent occurrence in gout of osteophytes, lipping of bone and the other morbid changes characteristic of osteo-arthritis, "and these changes are not peculiar to gouty joints, but are identical in nature and character with those which are produced by repeated and chronic inflammation of the joints from rheumatism or other cause."[20]

c. Rheumatoid Osteo-arthritis.—This is not a very desirable designation, but its meaning is sufficiently clear, for just as osteo-arthritis may follow in the trail of articular rheumatism and gout, so it may follow rheumatoid arthritis. One or two writers[21] contend that in such cases we have evidence of two distinct concurrent diseases, and deny that hypertrophy of bone ever occurs in rheumatoid arthritis as an integral part of it. Abstractly this may be so; clinically, the distinction is not of great importance, and it is doubtful if it can be maintained. In all chronic joint diseases a double process is at work: the one leading to atrophy and destruction, the other to repair and overgrowth. No doubt in childhood and youth, owing to the special proclivities at that age of certain tissues over others to become diseased, and their greater vulnerability to destructive agencies, the arthritic lesions may be altogether atrophic; but in those who rally and become well nourished in spite of the continuance of the disease, and in those instances where rheumatoid arthritis does not appear until middle life is reached, the characteristic osteophytes are often found in the affected joints.

Of course as to all these cases following rheumatism, gout, rheumatoid arthritis, and other toxic diseases, it may be asserted that we have one distinct disease following another, as tuberculosis may follow measles. The weight of evidence however is in favor of the view that the osteo-arthritis is not due to the introduction of any new element of disease, but that it is simply the effect of the lingering irritation of the tissues of the joints by the toxins of the primary disease from which the patient has never recovered.

II. Nutritional.—In certain hypertrophic affections of the bones and joints, there is imperfect or perverted nutrition. In rickets, accompanying the defective ossification, due to the lack of certain necessary elements in the food, there is frequently hyperplasia as well, and among the bones so affected are the long bones with their articular ends. This hyperplasia of bone is suggestive of the existence of a subacute or chronic inflammation, a view supported by the experiment of Kassowitz, who produced a state of bone corresponding to that of rickets, by inducing hyperemia in the limb of a growing animal by means of repeated applications of an Esmarch bandage; but it may be owing to the impetus of the formative process expending itself abnormally, because thwarted in its normal direction from the want of proper material.[22]

Another very important factor in constructive metabolism is the internal secretion of various glands. Any abnormality of these may cause overgrowth of tissue, and apparently, pathological alterations in one gland produce alterations in the others.

In acromegaly, which depends according to our present knowledge, upon disease of the pituitary body, hypertrophy of the thyroid gland, and the functional persistence of the thymus gland, in addition to the characteristic enlargement of the bones of the head, feet and hands, there is a tendency in all the bones to exaggeration of normal ridges and tubercles, and to the formation of osteophytes in the neighborhood of the articulations. The aberrant growth of the bony skeleton in gigantism depends upon a very similar condition, as proved by a recent instance in which there was an epithelioma of the pituitary body and hypertrophy of the thyroid gland.[23] So also at the other pathological extreme. In a dwarf, though the long bones were diminished

in length, "the articular ends were swollen into irregular globular masses," and Hektoen, who describes the case very fully, found the pituitary body and thyroid gland abnormal.[24] Mendel calls attention to the great similarity between the symptoms exhibited by dogs whose thymus glands have been removed, and those of rickets in children, and quotes another observer, who ascertained as a positive fact that in all rickety children, there is something wrong with the thymus.[25]

In osteomalacia, a disease which seems to be in some cases dependent upon an abnormal condition of the ovaries, as it has been cured in several instances by their removal,[26] the atrophied bones are in many parts encrusted with osseous deposits. This leads to Brown-Sequard's theory that all senile change, which necessarily includes the proneness of the tissues to calcification and ossification, depends upon the loss or diminution of the generative functions. In the French giant Constantine, who died recently at the age of twenty-nine years, the genital organs were atrophied, and sometimes they are atrophied in acromegaly.[27] Wieting states that the lack of regulative influences from this condition, as in eunuchs, is responsible for overgrowth of the skeleton, reporting in detail the case of a young giant almost nine feet high.[28]

From all this it is evident that whenever there is osseous hyperplasia which cannot be traced to any other cause, there is a possibility of one or other of these glands being at fault. The precise action of their secretions is not yet fully explained. Perhaps they do nothing more than regulate metabolic processes, preserving the normal balance between repair and waste; or what is more likely, they may have the power of destroying or converting into harmless compounds, certain poisons the product of cellular activity, which, if allowed to remain in the system unchanged, act as irritants and stimulate the tissues to overgrowth.

III. Osteo-arthritis of Traumatic Origin.—A large proportion of the cases of monarticular osteo-arthritis are due directly or indirectly to some form of traumatism. In many instances the injury falls upon the tissues predisposed to osteo-arthritis by advanced age, or by some antecedent disease such as syphilis, tuberculosis, gout and rheumatism; but that abnormal growth may follow an injury of tissues previously quite healthy, is proven by the large nodes from this cause on the antlers of stags.[29]

The injury causing osteo-arthritis may be sudden and direct, as a blow, sprain, fracture or dislocation. Extremely heavy labor throwing an excessive strain upon the joints will also produce it; this occurs with great frequency in horses as well as in human beings.[30] A milder form of the same morbid process is seen in the thickened phalangeal joints of washerwomen, and of ardent baseball players. The irritation arising from the presence of a foreign body in the joint, such as the fragment of a needle, will cause osteo-cartilaginous overgrowth.[31] In hemophilia, the mechanical irritation from unabsorbed blood clots in joints which have been the seat of repeated hemorrhages must be an important factor in starting the morbid process which ends by making such joints typically osteo-arthritic.[32]

Injury or irritation of any and every kind is thus capable of starting an osteo-arthritis in man and the lower animals. In this connection it is interesting to note that the lower the form of life, the greater is the tendency to excessive growth after injury; and as an evolutionary corollary, the tissues of the human body which show the greatest potentiality for reproduction when stimulated by injury or inflammation, are those which are the least highly organized and most widely distributed, such as cartilage, bone, and the other tissues of the connective tissue group. Indeed, comparative anatomists now tell us that our bones are merely the half dead calcified framework of the body, built up largely from waste material, and therefore of the same lowly excretory origin as the shell of the oyster, and the chitine armor of insects and crustaceans.[33] In the oyster itself we can see the effects of irritation by comparing the thin, smooth shells of those which have lived in quiet shallow waters, with the thick, rough, laminated shells of oysters which have to contend with the pressure and buffeting of the deep sea.

The great majority of traumatic cases of osteo-arthritis are found among elderly people, and as "malum coxæ senilis," and "senile arthritis," are terms still commonly applied to them it is necessary to examine these senile cases a little further. "But what a relative word senility is. In medicine we do not count the ages of people by the revolutions of the earth around the sun, but we measure them by the involutions of their own morbid processes." A man may be prematurely old in his joints as well as in his arteries.

But in spite of the fact that few old people escape a touch of rheumatism in one form or another, there is of course no such condition as a purely senile arthritis. It is true that the bones in common with the other tissues of the body, undergo certain atrophic changes which are part of the normal involuntary process of the skeleton in old age; but in the absence of disease and injury, the bones as a rule retain their general size and form, simply becoming thinner, lighter and weaker. Even the commonly accepted statement that the angle between the neck and shaft of the femur becomes smaller with age, does not hold true of the normal subject, at least this alteration does not invariably take place. At the same time a very slight injury seems sufficient to start an osteo-arthritis in adanced life, as shown by the fact that osseous anchylosis of the vertebræ is often found post mortem, of which no complaint was made during life, so imperceptible was its course. In these senile cases, no doubt other factors beside the excessive reaction to injury, contribute to the hyperplasia, such as the narrowing of the channels which

remove waste products; the affinity of dying tissue for the lime salts in solution in the body, their combination with them, and subsequent organization into bone; and, possibly, the loss of regulative influences on metabolism resulting from sexual decline, a view which receives some support from the fact that in women, osteo-arthritis generally appears about the time of the menopause.

Lastly, to quote the polite intimation in Shakespeare to Jack Falstaff, who can hardly have escaped this disease, considering he had rheumatism, gout, syphilis and several others beside, osteo-arthritis is "blasted with antiquity." Evidences of it have been found in human remains almost prehistoric, and in the bones of animals now extinct. It has also an extremely wide zoological distribution. Blandford Sutton has detected the disease in the joints of a snake's backbone, in birds of various kinds including an ostrich whose neck was affected, in cats, dogs, leopards, lions, tigers, horses, oxen, sheep, kangaroos, bears and many other animals.[34] It has also been observed in the vorqual, a species of whale.[35] The precise cause of the disease in these animals can only be conjectural, but we can be quite sure that it does not depend to any large extent upon habitat, nor can it be due exclusively to any particular form of diet.

Summing up the etiology of the disease, it is evident that whenever the tissues of the joints suffer from some low form of chronic inflammation following disease or injury, or are kept in a continual state of irritation from overstrain or from the presence of foreign substances in the joints, or their nutrition is impaired by some glandular disturbance, then osteo-arthritis may occur. We cannot say it is altogether a disease of toxic origin but as "toxic substances wreak their heaviest vengeance on the joints," it is in those diseases in which toxins are formed abundantly, that we may expect to find osteo-arthritis, and as a matter of fact do most frequently find it.

The point gained in proving osteo-arthritis to be simply a secondary affection, is that by inseparably linking it with the primary condition of disease or injury, a large number of cases of joint disease which at present stand unrelated and in confusion, are definitely grouped, and the classification of joint diseases becomes at once more intelligible and orderly.

Treatment.—General.—The medical treatment is that which is appropriate for the primary condition. Whatever source of systemic affection there may be must be removed and the toxins eliminated from the system.

Drugs such as the alkalies are often prescribed in this disease for the purpose of eliminating from the system uric acid supposed to be in excess. They may do good by combating intestinal fermentation, but according to recent researches it is extremely doubtful if they combine with uric acid in the human body as precisely and energetically as they do in the chemical laboratory. Even if they do, they are only useful in those cases of osteo-arthritis with the gouty diathesis. The salicylates may be given in the rheumatic cases for the relief of pain. Except from the use of mercury and the iodides in syphilitic cases, no drug that the writer is aware of, is capable of reducing to any appreciable extent, the enlarged bones of this disease. Much may be done, however, to check their growth especially in those cases wherein the internal glandular secretions are defective, by giving preparations of the glands which are in fault. The dietary is important. Bezley Thorne, of London, who has had a very large experience in the treatment of this disease, informs the writer that he puts his patients upon what is practically an antidiabetic regimen, and gets good results. Change of climate is often beneficial and a prolonged visit to any of the well-known thermal springs will very greatly improve the patient's general condition.

Local.—Many of the cases of osteo-arthritis find their way to the osteopaths whose vigorous manipulations occasionally do good, but often work great harm. It stands to reason that as long as irregular nodules of bone and cartilage are in the course of formation on the articular surfaces of the joints, even ordinary wear and tear, much more the violence of osteopathic exercises, will stimulate to still greater osseous development. In the early stages of the disease, rest and alleviation of pain are necessary. To obtain the former, mechanical measures for the relief of interarticular pressure, and even for immobilization of the joint may be required. Yet this phase of treatment must not be unduly prolonged, or the tendency to permanent stiffness will be increased. As soon as possible after all acute inflammation has subsided, the joints should be given baths of superheated dry air, followed by gentle passive movements of the joint and massage of the neighboring muscles, gradually increasing the range of motion during the exercises, but never so far as to cause severe pain and inflammation.

This form of treatment by improving the nutrition of the joint and removing the morbid products of the disease, often accomplishes a great deal in diminishing the stiffness, pain and general weakness, and the tendency to muscular atrophy.

In very advanced cases, the forcible manipulation of the joint under an anesthetic has occasionally effected temporary improvement, but, as a rule, only in those cases where the stiffness and crippling depended on fibrous adhesions which were thus broken down. It is hardly advisable to attempt in this way to break off the osteophytes and push them out from between the articular surfaces, as such fragments will always be foreign bodies in the joint, and will probably cause irritation. The aim of all treatment must be to check the morbid process, keep the patient comfortable, and secure, as far as possible, freedom of movement in the joints. In advanced

cases the less that is expected, the greater will be the satisfaction with every gain in this direction.

BOVINE TUBERCULOSIS.

BY J. W. KIME, M.D.,

OF FORT DODGE, IOWA;

SUPERINTENDENT BOULDER LODGE SANATORIUM FOR TUBERCULOSIS, FORT DODGE, IOWA, AND 2727 WEST THIRTY-THIRD AVENUE, DENVER, COLORADO.

The exact relation of bovine tuberculosis to human tuberculosis is not yet made out but when this relation has been definitely ascertained it will no doubt be found to be a very close one.

The morphology of the bacilli is practically identical, the bovine bacillus being slightly shorter and a little thicker than that of human origin. They grow on the same media, take the same stains and each produces in many experimental animals the pathological changes common to tuberculosis. Of the two, the bovine bacillus is pathogenic for a wider range of animals than is the human bacillus and the morbid changes which follow its introduction are much more marked and the disease is much more rapidly fatal than is that produced by the human bacillus.

In a number of instances human tuberculosis has been experimentally transferred to cattle and, accidentally, a number of well authenticated cases of bovine tuberculosis have been transmitted to man. Hence, the two diseases must be held to be identical in man and in bovines, the only differences being those which might be expected in mammals differing so widely from each other.

Personally, I believe that the milk of tuberculous cows is just as dangerous as the sputum of the consumptive patient and that it produces fully as many cases of tuberculosis in man as come from bacilli of human origin; and it is very probable that those cases derived directly from the cow are more rapidly fatal than are those which have for a number of generations been confined to man. In other words, I believe that in the cow we find the natural habitat of the tubercle bacillus.*

This view is strengthened by the fact that in a very large percentage of the cases of human tuberculosis we are able to trace no source from which the disease has originated. My own records show that in fully one-half of all cases seen there is no history of tuberculosis in the family and the patients have not, to their knowledge, been at any time in close contact with the disease. They also show that there are fully as many cases from the rural districts as from the cities. This would not be likely to be so unless there were some prolific source of infection in the country.

It is estimated that there are in this country not less than 2,500,000 tuberculous cows, and from these, milk, butter and other dairy products are daily distributed to our homes. Of these products, milk is most dangerous as it is used in the uncooked state and is itself a good culture medium for the bacillus.

Milk from tuberculous cows is unfit for use no matter how slightly the cow may be affected and without regard to whether the udder is diseased or not. Of course the more extensive the disease, and the more the udder is involved, the more dangerous the quality of the milk. But if any cow respond to the tuberculin test she should at once be condemned for dairy purposes, as foci of infection may be present in the udder and may not be sufficiently large to be detected by any known methods of examination; nor is it known that milk from tuberculous cows whose udders are healthy is free from bacilli. In fact, the contrary is held to be true. Certain it is that all tuberculous cows are sick cows and no animal is suitable to furnish milk for use that is not in a perfect state of health.

Milk from an infected dairy herd is especially dangerous to children whose diet is so largely composed of this single article of food. It undoubtedly contributes largely to the summer diarrheas which are so common in infantile life and, if the child then escape, it may only be to be stricken down in early life by the same insidious germ which has lain latent for many years.

It is a well-known fact that cattle may be fat and sleek and to all outward appearances in perfect health and yet be perfect hotbeds of tuber-

* See author's paper "On the Natural Habitat of the Tubercle Bacillus," in New York and Philadelphia Medical Journal, Dec. 19, 1903.

culosis. The disease is less rapidly fatal in bovines than in man, probably because the germ is in its natural environment when in the tissues of the cow. Few cattle also are permitted to live sufficiently long to die of tuberculosis; few indeed are permitted to die a natural death from any cause, and not many live to the age of five years. Live stock men who have estimated this percentage for me say that not more than two per cent. of cattle escape the butchers' block.

By the tuberculin test only may it be ascertained whether cows are suffering from tuberculosis and, so reliable is this agent, that all cows intended for dairy purposes should be tested with it by competent veterinarians at least once each year, while all additions to the herd should be tested before being permitted to mingle with the other cows. This will be done only when laws and ordinances require it before milk may be sold to consumers.

There has been an earnest effort on the part of physicians, veterinarians and other well-informed people during the past few years to stamp out tuberculosis in our herds of cattle and especially in those which supply milk to cities and towns, but these efforts have been met in many parts of the country by the most bitter opposition on the part of dairymen and live stock men. It has been feared by them that financial loss would follow should the presence of tuberculosis be found in their herds. A recent experience in this city fully demonstrated the spirit of opposition from these sources. As a result of local agitation, the State Veterinarian of Iowa tested the dairy herds supplying milk to the city of Fort Dodge, a city of some 15,000 inhabitants, and found that 25 per cent. of all the cows in these herds were tuberculous. They were condemned for dairy purposes and an attempt was made to have a city ordinance passed for the purpose of protecting the public against like dangers in the future. Able attorneys, also residents of the city and consumers from the dairies, were employed to oppose the ordinance and it was defeated. The public was wholly apathetic and one dairyman, who refused to have his herd tested, continued in business without the least loss of patronage, although he sold his milk at the same price as those whose herds were now known to be free from disease. Later a local butcher bought the condemned cattle and sold them on the block to the residents of the city. This fact was published by a local newspaper and did not even excite comment. And yet this is a community of average intelligence.

This public apathy presages a long and almost hopeless fight against tuberculosis in our dairy herds. So utterly hopeless was it here that I found it necessary for the protection of my own family to purchase cows for private use.

The flesh of tuberculous animals is less dangerous than is the milk, on account of the high temperature to which it is subjected in cooking. Meat taken raw, however, is but little less dangerous than is the milk, and the high mortality from tuberculosis among the American Indians is no doubt in large measure due to the inferior quality of the beef supplied to them by the contractors and which is consumed by them largely without previous cooking.

The pasteurization and sterilization of milk have no doubt saved many lives, not only from tuberculosis but from other diseases whose germs find their way into the milk. But the changes produced by heat are undesirable on account of frequent alterations in the taste, rendering it less palatable than in its uncooked state. If properly pasteurized, however, the change is scarcely perceptible. This is, of course, making the best of a bad bargain—doctoring the milk when the cow should be removed from the herd.

Tuberculosis is far less common among cattle on the open ranges than in those confined in barns, a fact which speaks volumes for free ventilation and life in the open air and sunshine.

The problem of bovine tuberculosis, and of a proper milk supply, is one of vast magnitude, involving millions of dollars on the one hand and many lives on the other, and much time and patience will be necessary in its solution. The unfortunate utterances of Koch at the London Congress of Tuberculosis have materially lengthened the time necessary to stamp out tuberculosis in our dairy herds.

NEURASTHENIA.

BY JOSEPH N. STUDY, M.D.,
OF CAMBRIDGE CITY, IND.

THIS name, which describes a group of mental and nervous phenomena, has at the present time, firmly established itself in the nomenclature of nervous and mental affections. The refinement and simplicity of modern times has brought forward this modern name from the various types of mental and nervous diseases.

Only a few years ago, Hammond and a score of other notable writers made no mention of this modern affection. At the present time medical journals are replete with articles upon this subject, and no up to date work upon the practice of medicine, nervous or mental diseases would be considered complete without devoting many pages, and even a whole chapter to its consideration.

Nerve weakness is nothing new, and probably existed in ancient times in some degree or form, and it is not at all improbable, but what all of the various symptoms establishing this new affection can be found under the various mental and nervous conditions.

Berkley says neurasthénia is primarily an affection of the nervous system, and that the disease belongs to the type of degenerative neuroses. That this condition is rapidly growing among all civilized nations is accepted as a truth beyond question. A quotation from Dr. Evarts does not seem to be altogether out of place here, who says, "That there is among mankind at the

present time, a large and increasing proportional number of persons of variously defective and abnormal mental capabilities and dispositions, and whose conditions are not pathological or amenable to medicine." This opinion will certainly be indorsed as true by a large number of observing physicians. As an etiological factor, it has been claimed that modern civilization, higher mental training, the struggle in life for financial and social standing, the many home and family cares, financial failures, and sudden mental and nervous shocks of various kinds, are contributing factors, as well as childbearing in women, and lack of wholesome, nutritious food, alcoholic drinks, syphilis, sexual excesses and masturbation have each and all been assigned as sufficient cause.

Dana says men and women are about equally affected, although he dedicates his chapter on neurasthenia as being synonymous with nervous women. Berkley thinks there is a preponderance of females. The Hebrews are said to be especially prone to this affection, while the Germans and French are much less affected, while the Americans perhaps lead all nationalities. It has been thought that city life, by the various features it presents, adds much to cause this condition, but cases are quite frequently seen in the quiet rural districts. In early life, young children frequently show lack of nervous stability, and in a measure are predestined to such conditions. Such children are prone to have convulsions from dentition, and other trivial causes. They are frequently quarrelsome, and as they grow older, given to various morbid impulses, and when the period of manhood or womanhood is reached, they are not well prepared for the activities of life, and frequently develop into one-sided men and women.

The lack of moral training in childhood, and the proper prompting and toning of judgment upon the developing mind and nervous system, and the want of good, sensible suggestions to the flexible mind, are without doubt factors which contribute to the bringing about of this mental and nervous condition. That heredity plays an important part in this affection in not doubted, and that an unstable, faulty, and defective mind, and nervous system is frequently the inheritance begotten by the union of one or both parents, who are neurasthenic, alcoholic, or syphilitic, which too frequently lies behind the affection to show itself in later years from appearently various and trifling causes. Dana says all women and many men are naturally endowed with a hysterical temperament.

The neurasthenic mind is not always a stupid, sluggish one, but very frequently the reverse. In men the perfect type is most often seen. In women the neurasthenic is often blended with hysteria, melancholia, and other types clinically have been designated as cerebral, spinal, genital, traumatic, acute hystero and gastric. The neurasthenic, like the hysterical mind, is very receptive, and frequently courts sympathy. It is entirely probable that a healthy, rugged mind and nervous system, in a healthy body, is seldom, if ever upset, even from extreme causes, and when so, it is most easily corrected. Improper suggestions to this class of afflicted people, at various periods of life, either by designing advertisers or not infrequently ignorant people, has something to do in preparing their minds for the final break down.

Too much stress is often placed upon the change of life by overzealous women, and no doubt that this constant looking forward to the inevitable period, when this awful crisis shall come, in some women has no good, but evil effects. Perhaps, too, that physicians have thoughtlessly, and possibly at times for mercenary purposes, suggested and treated this class of women for uterine and sometimes other imaginary difficulties, thereby rendering her a mental invalid, for a portion of her life at least. Organic diseases of the uterus, ovaries and appendages, seldom if ever, produce neurasthenia, unless it be by producing first a state of adynamia.

The conditions which best describe a well-marked case of neurasthenia seldom appear till the period of manhood or womanhood is reached, when the active cares and burdens of life have begun, when they increase up to the fortieth year, and sometimes the fiftieth year, after which cases are much less frequently seen.

The symptoms that the neurasthenic, or nerve bankrupt, may present for consideration are legion, and may almost exhaust the whole vocabulary of medicine, although there are most usually a few ailments that predominate. The vasomotor disturbances of the vascular system, the tumultuous beating of the heart, the dyspepsias, the genital affections and insomnia are among those proving very annoying. General weakness and lassitude are sooner or later complained of by many. The mental depression which frequently is present, has a tendency to diminish all of the secretions, consequently constipation, stomach and intestinal digestion are often complained of. The urine is frequently, but not invariably scant, and the specific gravity is high, and oxalates and phosphates are found in abundance. Sometimes various perversions of the special nerves of hearing, seeing and tasting are present, and the various catarrhal conditions are sources of much dread and fear. And the hyperesthesias and anesthesias are quite common. The various phobias sometimes add to the mental misery, a state of constant fear of various things, impulsive, almost irresistible desire for news, and even to read letters of others has been observed. Imperative, compulsory ideas may present themselves in the course of the daily routine of the neurasthenic, although Metler says there is a marked difference between the imperative conception of a neurasthenic who conceives the idea that he must not cross a certain thoroughfare or street, who laughs at his delusion, in contrast from the imperative conception emanating from

a diseased context to do a certain act which might be the slaying of his fellow-man.

The neurasthenic is not infrequently endowed with a jealous, unreasonable, sometimes a quarrelsome disposition, and from the long lists of tales of woe filed in divorce proceedings in our trial courts, it would not seem at all improbable, but that this class of individuals furnish their full quota.

In the differential diagnosis, the symptom complex of the neurasthenic may closely resemble and mask some very grave mental affections. And the differential diagnosis may require the most careful study and sound judgment. There are certain cases that may require excellent knowledge of the whole field of internal medicine before correct conclusions are reached.

The treatment of the neurasthenic should consist both of moral measures and medicinal remedies. No physician can accomplish much without fully gaining the confidence of his patient, and the physician's ability to restore his patient to mental and physical health will depend largely upon this proposition. The skill and tact and patience to successfully treat this class of individuals, who frequently are fairly shrewd, is fully as great as that required to treat a pneumonia or a typhoid fever patient. Moral treatment should always be enforced, supplemented by therapeutic agents of known value. The bromides sulfonal and trional are frequently used to meet certain indications, as well as strychnine, iron and phosphorus, or the glycerophosphites. Cascara, sagrada and pepsin are useful for constipation and indigestion.

One of the chief aims of the physician should be against polypharmacy, as these people think they need a remedy for every imaginary ailment. The Weir-Mitchell rest cure and massage has been successful in a certain class of cases. Alcoholics in some cases may be of benefit, but their indiscriminate use, as well as that of opium, morphine, chloral and cocaine, should command the earnest consideration of the physician.

Nutrition is frequently below normal, and a plentiful supply of well-selected and properly cooked food should always be insisted upon. Neurasthenic patients frequently drink too little water—an adequate amount should form the daily routine. Electricity in its various forms has not proven a cure-all but in some cases may be of benefit.

There are no pathological findings characterizing this condition. As to prognosis, Berkley says, "Most cases make a partial or complete recovery in five years, and that it is surprising how few of these cases pass into the more serious mental states." It has been my observation, that most all of these people regain their physical and mental status to a greater or less extent. Some favorable cases perhaps make a permanent recovery. Evidently large numbers go through life partial or complete invalids, imbibing patent and other medicines, looking for a cure and an ever-ready victim for the charlatan and patent medicine vendor. There are others who presumably cross the border line of insanity, and are known in their homes as queer or eccentrical individuals, or else find a home in some retreat, and it would not be surprising, that not a few end their earthly career by their own hands. The neurasthenic in general terms is an interesting patient, and is at all times worthy of our profound consideration, both as to his physical and mental health.

MEDICAL PROGRESS.

MEDICINE.

Auscultatory Percussion.—A number of articles have appeared recently in German literature which tend to throw discredit upon auscultatory percussion as applied to the heart. Entirely faulty boundaries are obtained, it is assumed, and the varying tension of the skin will permit the percussion of heart-shaped figures even over other parts of the thorax. A. SMITH and J. HOFMANN (Münch. med. Woch., Dec. 15, 1903) assert that this is due to faulty technic. They have made hundreds of examinations and have controlled the accuracy of the method by means of the X-rays. Considerable experience is required as skin-tension must be carefully avoided; the stroking should be practised with a fine brush, or, better still, with a small drum which is rolled over the chest and to which a brush is attached. Various drugs, warm baths, etc., undoubtedly cause a change in the cardiac contours.

Albuminuria of Puberty.—It is not generally known that a large percentage of boys from fourteen to eighteen years of age suffer from albuminuria without having nephritis. F. LOMMEL (Deutsch. Arch. f. klin. Med., Vol. 78, Nos. 5 and 6) had the rare opportunity to examine repeatedly over 500 young employes of a large factory and discovered albumin in no less than 19 per cent. In most cases, only traces could be detected, though in a few the amount exceeded 1 pro mill. The greater part of the albumin seemed to consist of globulin as in acute nephritis, indicating the presence of wide meshes in the filtering apparatus of the kidney. The cause of the albuminuria, which generally had an intermittent character and was orthostatic in type was to be found in an impoverished condition of the blood, together with a mild degree of cardiac insufficiency and tendency to stasis, such as is liable to occur during puberty where the rapid growth of the body is out of proportion to the functional powers of the internal organs. In accord with this, dilatation of the heart, tension of the arteries and accentuation of the second aortic sound were frequently noted. The condition is readily outgrown, since it was not found in any of the men above twenty-five years old of the same factory. It is often difficult to distinguish from chronic interstitial nephritis, but the slight amount of albumin, the rare occurrence of casts of hyaline character and the distinct intermittent type speak against the latter. Moderate cardiac changes are of no value as they occur in both.

Osmotic Pressure of the Blood.—The osmotic pressure of the blood is a constant factor, expressed by a definite freezing-point and regulated by respiration, metabolic activity and renal excretion. Respiration removes carbon dioxide which normally lowers the freezing-point, and the kidneys excrete certain molecules which would have the same effect. A. LANDAU (Deutsch. Arch. f. klin. Med., Vol. 78, Nos. 5 and 6) has studied the congealing point of blood-serum under various conditions, in order to determine to what ex-

tent this may be looked upon as index of renal function. Unfortunately his results tend to minimize the practical importance of cryoscopy. It appears that food has little influence; thus, with a strict milk diet, normal figures were obtained, though the serum was considerably poorer in nitrogen than before. This nitrogen loss depended upon a deficiency of albumin; since albumin, however, consists of very large molecules, no variations in the freezing-point can be expected. After the use of thyroid tablets, the osmotic pressure became subnormal, due to reduction in chlorides, secondary to more active metabolism. In Bright's disease an increased osmotic pressure, manifesting itself in a freezing-point below —0.58° C. seems to point to a retention of excrementitious products, but normal figures indicate renal sufficiency only if the serum is not poorer in nitrogenous substances. Even in uremia and advanced nephritis, cryoscopy may give no clue as to the condition of the kidneys, since a dilution of serum occurs which compensates for any change. This fact will limit the usefulness of cryoscopy in surgery considerably, unless accompanied by a chemical examination of the serum. Occasionally the latter will also yield normal results in nephritis, but here the compensation is perfect. The influence of fever, as in typhoid, pneumonia, etc., is not constant, as the pressure may be normal, increased or diminished without any relation to the nature of the disease. In diabetes, the freezing-point was generally found subnormal, owing to the presence of glucose, acetone and diacetic acid in the serum. In pernicious anemia, the serum congealed at a somewhat higher temperature than normal, owing to larger amount of water present.

Gastroptosis.—A careful clinical study based on 28 cases of this condition has been made by J. D. STEELE and A. B. FRANCINE (Univ. Penn. Med. Bull., Dec., 1903). Their cases have been kept under observation for more than a year and their conclusions have been formulated in answer to two questions: To what extent is gastroptosis responsible for symptoms? and of what value is prolonged external mechanical support as a means of treatment? As regards the first they find that their cases naturally fall into two divisions, first those in which gastroptosis is a primary condition and those in which the gastroptosis is not the main factor in the morbid state. They find that certain cases are relieved so promptly by external mechanical support alone, without any other treatment beyond regulation of the diet, that the downward displacement of the pylorus must be regarded as the primary or at least the principal factor in the causation of the symptom complex. Cases of this character exhibited a moderate diminution of hydrochloric acid secretion, were free from organic disease, and showed no signs of dilatation or impaired motility. The symptoms were those of malnutrition, gastric fermentation, attacks of frontal headache, and sensations of dragging and lack of support in the abdomen. Gastroptosis may exist absolutely without symptoms. This is shown by the demonstration of downward displacement of the pylorus in the routine examination of other morbid states. Such patients were not benefited by external support, and recovered completely, although reexaminations showed that the stomach was still displaced. Gastroptosis may form part of the symptom complex of other morbid states, such as neuroses, gastric motor insufficiency and dilatation, and passive congestion of the stomach from weakness of the cardiac muscle. Here the downward displacement of the pylorus is also relieved by a mechanical support. The value of the mechanical support was not exerted in restoring the organ to its normal position as shown by repeated examination after the belt had worn for considerable periods of time. It apparently produced some change in the organ which enabled it successfully to perform its function, although displacement still existed. These changes were probably compensatory in character.

SURGERY.

Method of Suturing the Prolapsed Kidney.—The technic, which has been developed in this very important operation, may now with fairness be regarded as having reached a stable equilibrium. AUGUSTIN H. GOELET (Ann. of Surg., Dec., 1903) states that the essential points in determining success are as follows: (1) The colon must be completely detached from the kidney, so as to obviate subsequent dragging upon it. (2) Reattachment must be prevented. This is accomplished by packing a gauze drain beneath and in front of the kidney and by early evacuation of the bowels. (3) The sustaining sutures must be inserted under the fibrous capsule in a manner to obviate tearing or cutting through that structure when they are tied, and the suture material should be one that is permanent. The suture should not be tied to the muscles, but should be brought out upon the surface of the back. They should not be removed until sufficient time is allowed for firm attachment. (4) The kidney must be restored to its normal position, and should not be attached lower down where it may be compressed by the corsets or other clothing. (5) The detached redundant fatty capsule must not be permitted to come between the kidney and the structures to which it is to adhere. This may occur after closure of the wound, and is another indication for the packing of gauze around the lower pole of the kidney. (6) When both kidneys are operated upon, the patient must be kept strictly on her back during three weeks. When one has been sutured, she should be turned upon the affected side only. (7) The operation is indicated before the patient's health is seriously impaired and before the kidney has become diseased. A vertical incision is made through the skin to the first layer of muscles beginning just below the last rib and extending downward along the outer border of the erector spinæ muscle for 3½ inches. The latissimus dorsi is separated in the direction of its fibers. The fascia is next divided and the quadratus lumborum exposed. This is drawn inward. The transversalis fascia is next split downward by traction, which avoids wounding the iliohypogastric nerve and vessels. The fatty capsule bulges up into the wound. The kidney can now be located with the finger and delivered. The fatty capsule is opened with scissors and is completely detached from the kidney back to the hilum. The fibrous capsule is not split or detached from the kidney, nor is it scarified. Firm adhesion can invariably be secured if the kidney is held immovably in contact with opposing structures. To accomplish this, silkworm gut is a *sine qua non*. Two sustaining sutures are inserted upon the posterior aspect of the free border. These penetrate only beneath the fibrous capsule and are so placed that when traction is exercised upon them they will not tear out nor give way. The suture differs in several details from the Brodel stitch and is considered by the author vastly superior to it.

Temperature in Shock.—Any experimental work which elucidates this little known condition is welcome. GUY C. KINNAMAN (Ann. of Surg., Dec., 1903), from a long and extensive series of experiments, whose scope and number lend particular weight to his observations, concludes as follows: (1) Shock must not be considered as due to the lowering or exhaustion of one bodily function, but as a composite condition embracing an interference with the normal height of the blood pressure with the respiratory act and with a marked fall in the body temperature. That there is a relationship between

the fall in body temperature and shock is evident by considering (*a*) that in one series, the fall in temperature was the sole cause of shock; (*b*) that by continuous bath the temperature fell but one degree. The respirations increased, instead of diminishing, and the fall in blood pressure was greatly lessened. (*c*) That by raising the body temperature previously lowered in shock, the respiratory rate was increased and the blood pressure raised. Of the three factors concerned, the temperature commands the first place by its powers of production, limitation and amelioration of a composite condition—shock.

Excision of Forty-two Inches of Small Intestines for Chronic Intussusception.—Not because of the unusual length of gut resected, but on account of the failure of the Murphy button, which would have resulted more disastrously than it did, but for timely interference, is this case one of peculiar interest. F. C. WALLIS (Lancet, Dec. 5, 1903) operated upon a healthy married woman, aged thirty-two years. Previous to May, 1901, she had never been sick. She had never had diarrhea. Her illness began suddenly with a most acute pain in the abdomen, the cause of which she did not know. After a rest in bed there was subsidence of the intensity of the pain, but it was always excited by food thereafter. She described the attack as "a general turning round and round feeling in the stomach, followed quickly by vomiting." She had never passed blood or mucus, and she had about five of these attacks, the more serious ones lasting for about three weeks. At the time of operation, an indefinite mass was felt below and at the left of the umbilicus. The gut removed was all small intestine, and the two ends were united with Murphy's button, reinforcing sutures were put in in addition, every care being taken in the technic of inserting the button. Three weeks after the operation, the patient had an attack of pain similar to that which she had previously suffered from. Chloroform was administered and on palpating the abdomen, the button could plainly be felt in what seemed to be the descending colon. No button was passed and the pains continued. Three days later, under the X-rays, the button was seen to lie on the outer side of the right rectus. On the following day, the abdomen was reopened, and the button found four inches above the ileocecal valve. It was removed through a longitudinal incision. The button was somewhat larger than usual, it having been used because of the dilatation of the proximal portion of the gut. This is an interesting sidelight on the occasional failure of this most valuable device.

Treatment of Angiomata.—A simple method of treating this condition is suggested by CARL BECK (Jour. Am. Med. Ass'n, Dec. 26, 1903). He has used it successfully in a number of cases and the method consists in the general principle of transforming the masses of vessels gradually into connective tissue. This is done by a subcutaneous suture as follows: A thread of catgut is passed in a zigzag manner, first below the skin, then underneath the base of the tumor, then again underneath the skin, underneath the tumor, etc., until the tumor mass is included in this continuous suture. The latter is drawn tight and closed at the point of entrance of the needle. In this manner the circulation is shut off within the tumor but no gangrene follows, inasmuch as some blood can yet reach the parts not included in the suture. The mass soon grows smaller and the normal epidermis outside of these limits stretches considerably, but becomes elastic and grows again. This procedure is repeated until the tumor is diminished to the smallest possible nodule of connective tissue. The hard connective tissue masses are then excised and the edges carefully united. This treatment applies to all varieties of hemangioma, but in the arterial and mixed varieties it is necessary to ligate the largest afferent vessels in order to check the rapid growth. In one of the cases he reports being compelled to excise a portion of the common carotid artery.

Prophylaxis of Gastric Cancer.—An interesting contribution to this subject is made by W. A. KATZ (Deut. med. Woch., Vol. 29, No. 47). He calls attention to the fact that cancer is rarely found in that part of the digestive tract in which the chyme is of a soft consistency and believes that cancer would become much less frequent if the diet were restricted more to soft foods, as free as possible from solid substances. Thorough mastication should be insisted on, soft foods should be preferred and copious amounts of fluids taken when solid food is being eaten. The author thinks that by approximating the conditions in the stomach to those which exist in the duodenum, gastric cancer will become as much of a rarity as cancer of the small intestine.

Sterilization of Silk by Diffusion Currents.—It has been admitted that although water and alcohol have no disinfecting power alone, when one is added to an article impregnated with the other, the diffusion causes currents in and around the bacteria, which kill staphylococci in two minutes. J. AUSIN (Deut. med. Woch., Vol. 29, No. 46) has applied this principle to the sterilization of surgeon's silk. This is first boiled in alcohol, to remove all fat, impurities, etc. It is then set aside to dry and before an operation it is boiled in water for twenty minutes, then placed for five minutes in alcohol, then for five minutes in water and again in alcohol for twenty minutes. He has used this silk extensively and has not had a single case of stitch where it was employed.

Strangulated Meckel's Diverticulum.—An instance of this condition as a complication of typhoid fever and believed to be the only one on record, is reported by J. SAILER and C. H. FRAZIER (Univ. Penn. Med. Bull., Nov., 1903). At some time previous to the patient's present illness he had an attack of abdominal pain which was attributed to gall-stones. During the typhoid, symptoms developed which pointed to some acute trouble within the abdominal cavity in the region of the umbilicus. For these a laparotomy was done, when a strangulated Meckel's diverticulum was discovered. The latter was distended and twisted. The base was adherent to the parietal peritoneum. A ligature was thrown around the proximal end and the stump invaginated into the intestine. No perforation was found and the condition of the diverticulum probably accounted for all the symptoms. The patient died eighteen hours later as a result of peritonitis. The authors believe that at the time of the supposed attack of gall-stones a localized peritonitis occurred between the distal extremity of the diverticulum and the wall of the abdomen. Twisting of the former but without complete strangulation. During the typhoid the bacteria must have extended along the mucous membranes of the diverticulum, setting up an inflammatory process, which caused enough swelling to tighten the twists and produce complete strangulation, followed by an exacerbation of the inflammatory process.

Difficulties of Early Diagnosis of Peritonitis After Appendicitis.—There is no symptom, says L. MANSLAIRE (La Méd. Moderne, No. 35, 1903), that will inform us absolutely of the advent of peritonitis after appendicitis. Fever may be altogether absent, while chills are rare. The pulse is extremely unreliable, as it may be normal with pus in the peritoneal cavity, and much increased without this. The facies constitute an important sign but exceptions to the rule are frequent. A tendency to syncope and a change in voice have been mentioned but are altogether too indefinite to decide

so important a point. Of more importance are tympanites and inability to pass gas. The association of certain symptoms may be of some value; these are: changed facial expression, pains radiating toward navel, epigastrium or left and persisting despite the application of ice; dyspnea, restlessness, fall of temperature and a tendency to syncope.

Value of Blood-count in Appendicitis.—A severe criticism is carried by L. Rehn (Münch. med. Woch., Dec. 15, 1903) against the practice, becoming more and more common, of deciding upon operation in appendicitis, from the number of leucocytes in the blood. If it is certain or probable that the appendix is in an inflamed condition, it should be removed without delay. Daily blood-counts will never give a clue as to the true pathological condition and they may jeopardize the patient's life, as valuable time is lost. Curschmann, who inaugurated the practice, states that more than 25,000 leucocytes indicate pus but Rehn has found that a large abscess may be present both in early and in less recent, progressive cases, with much lower figures.

After-Treatment of Intranasal Operation.—The pain of these dressings so far exceeds that experienced in the primary operation that from the patient's standpoint a consideration of after-treatment is of great importance. Sir Felix Semon (Med. Press, Nov. 25, 1903) believes that tamponage, except in chosen cases, is apt to produce irritation, to cause local anemia of the injured parts and to prevent healing. A spray consisting of three grains of cocaine and half a dram of boric acid in six ounces of water was recommended for the reduction of inflammatory reaction. Tampons for the prevention of secondary hemorrhage are not valuable, since they do not prevent the occurrence of this accident when the tampon is removed the day after operation. In extensive wounds he introduces a strip of cyanide gauze soaked in peroxide. The patient should be directed to apply cold water compresses if bleeding occurs. Deep breathing with the closed mouth may also check hemorrhage. In general the author advises a let-alone policy, believing that the formation of cicatricial bands after operation is rare.

Diagnosis of Perforated Gastric Ulcer.—So many empirical rules have been laid down in this important matter that it is interesting to note how, with advance of our knowledge on the subject, little reliance can be placed in them. W. Harland Peake (Brit. Med. Jour., Nov. 21, 1903) says that for the general practitioner a knowledge of the indications, if any exist, of perforation, are of paramount importance. In considering the question of shock and collapse in association with pulse and temperature, he says that the so-called period of repose, which supervenes soon after perforation and in which the patient feels better, is a reasonably constant factor. Mitchell believes that the shock in these cases is due either to the presence of gas in the peritoneal cavity pressing upon the diaphragm and so upon the heart, or to the disturbance of the great sympathetic ganglia and peritoneum by stomach contents. In support of this theory he has shown that certain cases with a pulse of 140 dropped to 96 and became strong after the opening of the abdomen when the gas pressure was taken off. On the other hand, in cases where little gas was present, the opening of the peritoneum made but little difference to the pulse. Liver dulness is now generally looked upon as an uncertain sign, its absence being frequently due to colon resonance or to a dilated stomach. The paroxysmal pain may persist for as much as 4½ hours after operation. Osler states that early vomiting is a prominent feature. Flagge alleges that it is the earliest symptom of acute peritonitis. Robson says that vomiting with or without bleeding is an inconstant symptom. Finny finds it recorded in 40 per cent., Fenwick in 29 per cent. Clifford Allbutt says vomiting is generally absent or soon ceases if it occurs at first.

Fracture and Separation of the Lesser Trochanter.—A fracture of this character has hitherto either escaped diagnosis or has not been reported, according to Chas. Juillard (Arch. f. klin. Chir., Vol. 72, No. 1). His patient was an old man who sustained an injury which was believed to be a fracture of the neck of the femur. Death from inanition came on shortly afterward and on autopsy there was disclosed a complete separation of the lesser trochanter, together with the iliopsoas muscle. The neck of the femur was intact. The symptoms were localized pain, ecchymosis and swelling, but most marked was the outward rotation of the leg. The author believes that it is impossible to differentiate this variety of fracture from that of the neck of the femur without the assistance of the X-ray. The prognosis, which of course cannot be determined from this isolated case, should be similar to that of fractures of the neck of the femur. He considers that the rational treatment ought to consist of fixation of the thigh in an attitude of flexion and slight outward rotation.

Forensic Importance of Appendicitis.—The peculiar course of appendicitis and the sudden development of perforation with fatal issue due to peritonitis, explains why the disease occasionally plays an important part in legal medicine, according to D. Kister (Friedreich's Bl. f. gericht. Med., Vol. 54, No. 6). A perforation may occasionally lead to a suspicion of poisoning: it may be caused by a rise of abdominal pressure such as follows even slight muscular exertion, where the walls are thin and eroded. Not rarely a distinct relation to trauma exists, so that the question of criminal assault may be an important one, but it must be remembered that an appendicular lesion has always existed. The severity of the symptoms stands in no relation to the degree of force used. Perforation of the appendix in suicides is rare.

HISTOLOGY, PATHOLOGY AND BACTERIOLOGY.

Primary Intestinal Tuberculosis.—Koch has recently made the statement that the intestines are very rarely affected primarily by tuberculosis and others have analyzed many cases and have come to the same conclusions. These conclusions are, however, erroneous according to O. Wagener (Münch. med. Woch., Dec. 1, 1903), since based upon the autopsies of adults. He examined the intestines and their mesentery of a large number of children who had died of some other disease and found tuberculous ulcers and cheesy mesenteric glands without other tuberculous foci in the body in as high as 21.1 per cent. In over three-fourths of these the specific stain for tubercle bacilli was positive so that there can be no doubt as to the nature of the lesion. In performing the autopsies, it is advisable not to sever the intestines from the mesentery, as small glands may be overlooked. Glands without ulceration in the intestines were never found.

Filariasis Cured by Removal of the Adult Worms by Operation.—This disease is extremely rare in this country and in Canada. A. Primrose (Brit. Med. Jour., Nov. 14, 1903) states that the embryo filariæ were first discovered in 1863. Bancroft found an adult worm in an abscess in a lymphatic gland of the arm in 1876. As early as 1877 Manson suspected the mosquito as playing the part of the intermediary host. In 1879 he demonstrated the life history of the parasite in the body of the mosquito. From further investigation it appears reasonably certain that the infection is communicated to man by the bite of the mosquito. On the west coast

of Africa, as many as 50 per cent. of the inhabitants are infected, but curiously enough it is rare to find these individuals ill. Nevertheless, occasionally the adult worms block the lymphatics. The embryo, too, may be responsible for these conditions, but under usual conditions they circulate freely in the blood and cause no disturbance of function. If, however, the parent worm be injured immature ova may be discharged in large quantities into the blood. They do not circulate as freely as the matured ova. They block the circulation and give rise to characteristic lesions. The case operated upon had the following history: It was that of a man forty-seven years of age, who had lived in Barbadoes all his life. In 1881, he was operated upon for what was thought to be hydrocele. Both sides of the scrotum were tapped and iodine injected. This apparently cured the condition. In 1884 he suddenly became seriously ill with fever and swelling of the leg. Two years later he had a similar attack. These attacks continued until the present date, but the period between them became progressively shorter. He had been infected for about twenty years. The scrotum was about three times the normal size, the amount of thickening being marked and permanent. The blood showed the characteristic signs of filariasis, one cover-slip alone showing 20 embryos. The specimens were withdrawn at night. The greater part of the indurated scrotum was removed, two lateral flaps of scrotal tissue being left. No ligatures were required. The wound healed without trouble. One parent worm, which looked like a piece of animated white thread about 6 cm. long was removed from the tissue. In salt solution it remained alive for some hours. Forty-six days after operation the patient developed elephantoid fever. A swelling developed in the neck which was incised and drained. Subsequent examination of the blood showed it to be absolutely free from infection six and a half months after operation.

New Reagent for Acids.—A reagent, appearing to be the most delicate as yet discovered for acids, is described by M. HEIDENHAIN (Münch. med. Woch., Nov. 24, 1903). It is the base of the aniline dye, nilblau, and is prepared from this by dissolving in alcohol and shaking with lime. The slightest trace of carbonic acid will at once turn this bright red fluorescing solution blue, and it is only necessary to blow gently upon its surface from a distance, to observe a beautiful play of colors. The atmospheric air, alcohol and even distilled water will be found to react acid with this base.

Etiology of Beriberi.—In the government asylum at Singapore the deaths from beriberi average 45 per annum, and the number of cases treated about 150. This was between 1887 and 1900. Since that date the disease has been nearly stamped out. W. G. ELLIS (Brit. Med. Jour., Nov. 14, 1903) states that by thorough cleansing and disinfection and the construction of two wards on the sea-beach four miles from the city, which have been used as isolation centers, the disorder has almost ceased to exist. The most important mediums used for disinfection are sea water, sand and sunshine. All the patients are bathed for at least half an hour daily and are kept out of doors all the time. They are freely massaged and are given strychnine, iron digitalis, and purgatives. All the patients are fed on Siamese rice. Thirteen years ago he separated 20 healthy native patients, giving them European food exclusively and no rice. In less than three months half the cases had developed beriberi. He then concluded that the disease was a place disease; that the soil and buildings were infected, and that this poison was the cause of beriberi. Siam rice is not the cause of the disease, as is shown by the fact that some time ago on a well-found steamer carrying 28 Malays and 51 Chinese hands, all of whom were fed on Siam rice, beriberi broke out among the Malays. Had the rice been in fault it is difficult to understand why the cases which broke out should all have been located in one cabin, as they were, and why the remaining 65 hands should all have entirely escaped. The conclusion is that rice has nothing whatsoever to do with the disorder and that it is purely of an infectious origin.

Elastic Tissue of Liver in Infectious Disease.—T. MIRONESCU (Virchow's Archiv, Vol. 174, No. 2) finds that in hepatic tuberculosis the elastic fibers may or may not be destroyed, depending on whether or not an exudative process is present. In hepatic syphilis there is a new-formation, in erysipelas a destruction of elastic fibers. In all other acute infectious diseases studied the changes were slight or absent.

Melanin and Glycogen in Melanotic Tumors.—In a number of non-melanotic malignant tumors, glycogen was found by D. HELMAN (Arch. internat. de Pharmacodyn. et de Therap., Vol. XII, fasc. III and IV) in such large amounts that the quantity could be readily estimated. A series of melanotic tumors was then examined with negative result. The amount of melanin was occasionally very high (7.3 per cent.), but the metastases often contained less than the primary tumor. The pigment does not seem to be constant in composition, for sometimes both iron and sulphur were present, while at others, only one of these elements. In general, four classes of pigment may be recognized, viz., physiological melanin, occurring in negro skin, the choroid and hair; pathological melanin of malignant tumors; artificial melanin resulting from the action of mineral acids on proteids and pseudomelanin, such as formalin pigment, the pigment of anthracosis and siderosis, etc. Microscopically the second class occurs in the form of amorphous, dark-brown granules, both in the cells and the connective tissue. The tumors are especially malignant and generally start from normally pigmented sites, though there are cases on record where the primary growth was free from pigment and the internal metastases rich in melanin. Some consider the tumor-cells epithelial in character, others believe them of endothelial origin and a marked difference of opinion also exists as to the relation of the pigment to hemaglobin. Since, however, dark granules often occur in the embryos of the lower animals and albumin can be converted into a dark mass by prolonged boiling, the presence of blood is probably not necessary. The pigment-formation is connected intimately with the functions of the suprarenal gland, which modifies the albumin so that it can be deposited as melanin in other parts of the body. The relation between glycogen and melanin is not clear but possibly the former enters into the molecule of the latter. Patients suffering from melanotic tumors often discharge a urine containing the mother-substance, melanogen and turning dark on exposure. Chloride of iron, bromine water and chromic acid will here give a black precipitate which does not, however, occur in all cases nor is it specific for melanotic tumors, since it is also found with ochronosis. Sodium nitroprussiate, potash lye and acetic acid often causes a blue discoloration which is still more inconstant. In the final stages of diabetes, the urine sometimes reacts positively, though melanotic tumors are not present. The melanin tests are of absolute value only where a melanotic tumor has been extirpated and melanuria persists or appears soon after, when a metastasis is certain. Melanin introduced subcutaneously is completely reduced by the organism, especially by the hepatic cells, so that it cannot be detected in the organs microscopically. For-

eign melanins, such as sepia and the coloring matter of peat, behave similarly. They are hardly toxic, except in very large doses, when convulsions appear in frogs and general asthenia in higher animals. Absorption does not take place from internal administration and injections are not necessarily followed by disappearance of glycogen from the liver.

Extra-uterine Malignant Deciduomata.—The history and pathological findings of the two cases observed by O. Busse (Virchow's Archiv, Vol. 174, No. 2) are interesting in that they prove that malignant deciduomata may also occur in places other than the uterus. The first patient was seized two weeks before death with severe headache, gastric symptoms, lassitude and cardiac pain and coma; involuntary discharge of urine and feces and facial paresis soon followed and one-half of the body became anesthetic and the seat of peculiar vasomotor disturbances. This vague symptom-complex was only cleared up at autopsy when it was found that both small and large vessels of the brain were completely occluded by emboli of varying date which had caused extensive softening of cerebral tissue. The cause of the emboli was a large tumor situated in the left ventricle of the heart which was made up of elements found only in malignant deciduoma. While most other organs were also riddled with metastases, the uterus was entirely free from pathological lesions so that the cardiac tumor must be looked upon as primary. The case is difficult of explanation but since there was a history of pregnancy five months before the onset of the illness, it is possible that portions of the placenta were torn off and carried to the heart where they were arrested by the slowing of the blood-current due to a beginning syphilitic myocarditis. In the second patient the malignant deciduoma had developed in the right parametrium and posterior wall of the vagina; the uterus was also free. At present, only sixteen cases of extra-uterine deciduomata are reported in literature; in most the primary tumor was seated in the vagina and metastases had formed in the lungs and brain. The mucous membrane of the uterus frequently swells like in extra-uterine pregnancy, but it is difficult to say if this depends upon chemical or reflex influences. The author does not share the common belief that metastases may disappear after extirpation of the primary tumor.

Tumors of Gärtner's Canal.—In the lower part of the cervix uteri, Gartner's canal possesses a dilated portion which begins to branch in the later fetal months. This portion is homologous to the male ampulla of the vas deferens but never possesses a pouch corresponding to the seminal vesicles. The difference in form between male and female ampulla is probably due only to mechanical causes since the firm cervical tissue restricts development. The most common tumors, according to R. Meyer (Virchow's Archiv, Vol. 174, No. 2) are adenomatous in character, taking the form of small, narrow canals and vesicles at the ends of the lateral twigs. They may be present at birth and are generally without significance. Most cases of cervical adenomata which do not start from the mucous membrane, belong to this class. Occasionally the surrounding tissue participates and the tumor has more the character of an adenomyoma. Malignant tumors are exceedingly rare; in fact the author's case is the first instance of carcinoma on record.

Nature of Blood-Plates.—When fresh blood is allowed to mix with concentrated solution of corrosive sublimate, the red corpuscles will develop a number of protuberances which closely resemble blood-plates and are by many considered identical with these. P. Schneider (Virchow's Archiv, Vol. 174, No. 2) concedes that both structures are very similar in morphology and in their relation to certain dyes, yet the plates cannot be looked upon as forming from the erythrocytes, since the former are not affected by 5 per cent. acetic acid, while the latter readily dissolve. The plates consist almost entirely of nuclear substance, while the red cells contain only traces of this in their stroma. It is still possible, however, that physiologically certain portions of the erythrocyte are extended and then undergo chemical changes, so that the experiments are not conclusive. Ameboid movements and nuclear substance do not absolutely prove the independent cellular nature since cell-extensions may develop both.

A Rapid Method of Imbedding and Hardening.—The modification of the Lubarsch method proposed by A. Stein (Deut. med. Woch., Vol. 29, No. 44) is as follows: The tissue is placed for five minutes in 10 per cent. formalin, for the same time in 95 per cent. alcohol, then ten minutes in absolute alcohol changed once, finally fifteen to twenty minutes in anilin oil until entirely cleared. These procedures are done in the incubator at a temperature of about 50° C., which is now increased to about 60° C., while the specimen is placed in xylol for 15 minutes, changing the fluid several times, and finally in paraffin for ten to thirty minutes. The entire process takes less than 1½ hours. It is applicable to sections not more than 3 mm. thick.

A New Cervical Dilator.—One of the chief criticisms to be made of the Bossi dilator is that its mechanism is very complicated and so many levers and screws are necessary in its construction that it is practically impossible to take it apart for cleaning. F. A. Higgins (Jour. Am. Med. Ass'n, Nov. 28, 1903) has devised an instrument which it is claimed overcomes these objections but yet retains one of the best features of Bossi's instrument, the removable tips. This admits of an instrument with a small point for use at the beginning of dilation. The dilator in question has five blades, the tips of which are made to spread by an advancing cone moved by a screw and a handle. The parts are limited in number and can be readily separated for cleansing purposes. The reason for using five arms is, that in this way the pressure is better distributed, no two arms coming directly opposite to each other. It may be necessary to precede the use of this instrument by the introduction of a moderately sized Hanks dilator and aside from its employment in obstetrics he has also found it of value for dilatation for curettage.

Action of Diphtheria Toxin upon Circulation.—According to K. R. v. Stejskal (Zeitsch. f. klin. Med., Vol. 51, Nos. 1 and 2) the poison of diphtheria acts upon the vessels as well as the heart. With the latter there is first an irritation and then a paralysis and general disturbance of the nervous mechanism; with the former a decrease in tensions developing to a complete paralysis, takes place. Both actions are simultaneous and independent of each other. The period of latency and degree of toxicity depend upon the size of the dose and also upon the individual resistance of the animal. If an animal is in poor condition, a normally non-toxic dose, will readily kill. The vasomotor paralysis will only react upon the heart to a slight degree in that the coronary vessels are less filled with blood; the anemia of the respiratory center is, however, of more important consequence than that of the heart muscle.

Long Bacilli of Gastric Cancer.—If the stomach-contents of cases of carcinoma of the stomach be examined, the characteristic long bacilli will often be found in nearly pure cultures. This G. Sandberg (Zeitsch. f. klin. Med., Vol. 51, Nos. 1 and 2) attributes to a special resistance of the germ toward high percentages of lactic acid, which inhibit the growth or destroy all the other organisms in the stomach except yeast. When grown on acid-free media, short rods are

usually obtained, but as soon as other lactic acid producing bacilli are present or they themselves are able to produce lactic acid, then length increases materially. Both long and short forms give characteristic colonies, but one may be changed into the other by modifying the conditions of growth and transition forms are common.

OBSTETRICS AND GYNECOLOGY.

Extra-uterine (Ovarian) Pregnancy.—Of the extra-uterine pregnancies those of the ovarian variety are comparatively rare, and Schrenck found in 610 cases of extra-uterine pregnancy but 4.6 per cent. of ovarian cases. G. I. OLECHNO (Roussky Vrach, Oct. 25, 1903) describes an interesting case of a woman, a primipara, aged twenty-five years, who asked for admission to the hospital because of a severe hemorrhage of three weeks' duration. Examination of the abdomen elicited a somewhat tender swelling, the dimensions of which could not be clearly made out on account of the woman's greatly developed adiposity. The uterus was in its normal position, and the size of a lemon, soft, and admitting freely a sound for 14 cm. The tubes were felt slightly enlarged; to the left and behind the uterus was a movable, slightly tender swelling, the size of the fist. A diagnosis of extra-uterine pregnancy was made, and a laparotomy was performed. A dark-red tumor, somewhat adherent to the broad ligament, was found in Douglas' cul-de-sac. The left tube was seen at its entire length, its fimbriated extremity grown to the antero-superior portion of the swelling. This last was separated from the surrounding adhesions and removed. As the right tube was also found to have undergone some changes, part of it was excised, the cul-de-sac was cleared of the clots, the wound closed, and a sterilized tampon placed in the vagina. Recovery was uneventful. The tumor contained a fetus with clearly demonstrable extremities. Its upper wall contained a hard body, which in its consistence and form felt like an ovary. The ovarian ligaments were not evident. With the pregnancy there was also a right hematosalpinx which escaped the notice of the examiner before the operation.

The Physical Chemistry of the Blood in Pregnancy, Parturition and Puerperium.—During pregnancy there is a rise in the freezing-point of the serum, according to G. FARKAS and E. SCIPIADES (Pflüger's Archiv, Sept. 8, 1903), which indicates a decline of molecular concentration. Following labor the serum reaches or exceeds the normal average concentration. During the above three periods the electric conductivity of the serum is subject to no variation, which indicates a uniformity in the concentration of the electrolytes. Toward the end of pregnancy and during parturition the concentration of the non-electrolytes, excepting albumin, which corresponds to the organic non-albuminous constituents, suffers a reduction. The content of albumin and chlorine show no change. The authors find that the amniotic fluid is a hypotonic fluid containing traces of albumin, and is no simple transudate of the blood.

Fibromata of the Anterior Abdominal Wall.—Two kinds of tumors are usually encountered in the anterior abdominal wall, solid and cyst-like. But in general these swelling are rather rare, and especially so the fibromata; even very active surgeons can boast of having met but few of these. As an example M. N. POROSHIN (Roussky Vrach, Oct. 4, 1903) cites such a celebrity as Billroth, who, during a most prolific practice of twenty-three years in Zürich and Bern, altogether saw between 15 and 20 cases of tumors of the anterior abdominal wall. The case reported by the author was that of a peasant woman, of twenty-eight years, who had the tumor in the abdominal wall for the last seven months. The swelling began to grow rapidly, especially since patient became pregnant; she aborted on the fourth month. A laparotomy was performed, and a tumor weighing 500 grms. and of soft consistency was removed. Microscopically it proved to be a soft fibroma, which is also known as a dermoid tumor.

Pelvic Exudations.—More than 80 per cent. of these cases are due to childbirth, according to the statements of E. C. CARMICHAEL (Brit. Jour. of Obstet., Sept., 1903), and the remaining cases result from surgical operation. Exudations are most common in the lateral parametria, more especially the left, but are liable to spread to and involve the other parametria, showing a tendency to limitations along certain lines as some anatomical observations might not lead us to suppose. The majority of the cases no longer suffer from fever when they are admitted to the hospital, and the presence or absence of this symptom is not a definite indication of the appearance of suppuration. The presence of a leucocytosis affords us a more reliable means of diagnosis as to the presence of pus, and if the leucocytes steadily increase, on repeated examination, and especially if they reach the number of 20,000, or over, surgical interference is justifiable. The majority of pelvic inflammations are cured by absorption or by suppuration. The most frequent cause of suppuration is the *Streptococcus pyogenes*. The hot air treatment has proved a very valuable addition to the treatment of this condition, more especially in large and chronic exudations, or in those patients where pain and discomfort result from cicatrices and thickening in the parametria, the remains of former inflammatory exudates. The chief contraindications to this treatment are fever, menstruation, and heart disease.

Müller's Operation for Uterine Prolapse.—Briefly stated, colpectomy, as described by Peter Müller, consists in excising the whole vagina and columnizing its bed, but—and this is the original feature in the operation—leaving the uterus behind intact. The idea, says R. P. KÖNIG (Brit. Jour. of Obstet., Sept., 1903), is to form compact cicatricial tissue in place of the vagina, on top of which the uterus is firmly imbedded, in its normal situation. Colpectomy can be done without general anesthetics in the vagina, being rendered insensible by Schleich's infiltration. The whole operation may be performed in ten or fifteen minutes. Müller advises that the older women be permitted to get out of bed as early as the fourth day to avoid any possibility from hyperstasis. The results of the operation are excellent. The author had not seen or heard of a relapse. The advantages of the operation are obvious: (1) The peritoneum is not opened, neither the bladder nor rectum is at any time endangered. There is very little traumatism and that not sufficient to produce shock. This then gives the maximum of safety. (2) It is a simple operation, the technic is not difficult, and the time consumed in performing the operation is short. (3) Anesthetics may be dispensed with. (4) Rest in bed for a few days is all that is necessary. (5) Recurrence is impossible.

Diabetes as Complication of Pregnancy.—A résumé of the cases in which this condition developed during pregnancy has been made by ALFRED STENGEL (Univ. Penn. Med. Bull., Oct., 1903), who also reports a case seen by himself. He has been able to collect 19 undoubted cases, with the diabetes present 27 times. It may have its onset in the first or in subsequent pregnancies. There seems to be a tendency to recurrence of the condition when it has been once established and the onset is apt to be early in the pregnancy. The symptoms are about the same as those in ordinary diabetes, the conspicuous ones being polyuria, increased appetite and thirst, weakness, loss of weight, boils and pruritus vulvæ. The author believes that the serious aspect of the prognosis has been magnified—among these cases 13 preg-

nancies terminated normally as far as the child was concerned, the remainder being miscarriages or dead fetuses. The maternal results show that in 27 pregnancies 17 terminated in normal recovery of the mother, in 5 death occurred soon after labor, and in the remaining 5 death occurred from diabetes or other causes within some weeks or months after the delivery.

Embryotomy as Applied in Transverse Dystocia.—A method which is applicable in cases where the neck cannot be reached, and therefore decapitation is impossible, is proposed by L. A. Herring (Medicine, Nov., 1903). He has used it with success in those cases where the shoulders lie deeply, the trunk is impacted and uterine rupture is imminent. The instruments required are a few bullet forceps, volsella, and a strong, straight episiotomy scissors. The fetal thorax is seized with two forceps placed side by side as it presents at the uterine orifice—if the arm is prolapsed or is in the way it may at once be amputated at the shoulder. The thorax is now opened in one of the intercostal spaces between the applied forceps and the latter reapplied so as to include the entire thickness of the wall. After enlarging the opening thus made, the heart and lungs are seized with a volsellum and removed by a twisting motion. The lateral incision is then carried backward until the spinal column is reached and cut through with the scissors. The hollow body of the fetus can now be made to sink downward so that all further manipulations may be made in the vagina. The entire thorax can now be cut through and then the two parts of the fetus may be readily extracted—first, the upper half and then the lower. The author claims that the procedure is not difficult and does not require any great amount of skill, and among the advantages is the fact that the hand need not be introduced into the overdistended cervix and add to the danger of uterine rupture. Moreover, when rupture is threatened, evisceration, according to the technic given, can be accomplished with much less intra-uterine manipulation than can version followed by extraction, there is no remaining head to consider after removing the trunk, as in decapitation, and owing to the exhausted condition of the patient, anesthesia can be dispensed with.

Volvulus in Pregnancy.—In case of sudden collapse during parturition, one must not lose sight of the possibility of volvulus. Where the ascending colon has an abnormally long mesocolon, this part of the intestine will often be displaced upward by the growing uterus. With the first pains the uterus will become erect and will cause the transverse colon to fall over the ascending portion. In the patient of F. Fromme (Münch. med. Woch., Oct. 20, 1903) the collapse was so sudden in onset that death set in shortly after forcible delivery.

Puerperal Streptococcus Infection.—The question as to whether the streptococci obtained from the genital tracts of pregnant and non-pregnant women are capable of producing septic infection during the puerperium, is still in abeyance. A confirmation of the view that the streptococci obtained by culture from the vagina and those from the blood of a patient with puerperal fever, are the same, might be obtained if both varieties showed similar behavior in cultural and animal experiments. A. Rielander (Zeitschr. f. Geb. u. Gyn., Vol. 49, No. 3) obtained cultures from two cases of puerperal infection after abortion and found that even large doses injected into animals manifested a very slight degree of virulence. Both patients were very ill, however, and in one case the woman died. In their cultural and morphological relations the species seemed to be the ordinary *Streptococcus longus*. These experiments prove that the streptococci found in the vagina, which are apparently harmless and do not produce pathological changes in animals, may under certain circumstances, at present unknown, result in severe infection of the human organism. This change may be due to growth with other bacterial varieties or to change in the soil on which they grow that offers a more favorable culture medium for the development of increased virulence.

The Mechanism of Posterior Occipital Positions.—The following is the mechanism thought to take place in these cases by W. B. Gossett (Am. Jour. of Obstet., Oct., 1903). In the R. O. P. position the occiput is directed toward the right sacro-iliac synchondrosis, the forehead toward the left acetabulum, the occipitofrontal diameter offering in the right oblique of the pelvis. The occipitofrontal diameter being longer than the right oblique of the pelvis, there is first flexion to allow the head to enter the brim, substituting the suboccipitobregmatic diameter of the head for the occipitofrontal. The force of the uterine contraction is transmitted through the vertebral column to the short pole of the fetal head, the occiput, so produces more flexion of the head. The head descends and the occiput, being the most dependent part meets the resistance of the pyriformis muscle and the soft parts as soon as it enters the brim. This resistance in the great majority of the cases (about 96 per cent.) starts the rotation of the occiput to the front, it rotating away from the point of resistance to that part of the pelvis where it has the least resistance, that is to the right and forward. This is the beginning of the second step of labor in R. O. P. position with a favorable termination, that is the rotation of the occiput through three-eighths of a circle to the front. The resistance of the pyriformis muscle and soft parts is sufficient to cause the occiput to fall in front of the dividing line of the two inclined planes that is a line drawn from the tip of the ischium to the ileopectineal eminence, and in front of the spine, so the resistance of the tip is back of the occiput, and the occiput rotates along the right anterior inclined plane and under the symphysis. If the resistance of the pyriformis muscle and soft parts is not sufficient to start the rotation of the occiput to the front, then the occiput will pass on down and fall behind the ischial spine and onto the right posterior inclined plane, following its direction, which is downward, backward and inward, to the hollow of the sacrum. The author does not believe that the occiput ever rotates forward after it passes posteriorly to the spine of the ischium. After it gets back of the spine it is hard to understand how it will rotate beneath the spine and to the front, or what will cause this rotation.

Treatment of Perineal Lacerations.—K. Hegar (Münch. med. Woch., Nov. 3, 1903) speaks strongly against the firmly-rooted custom of suturing tears at once or soon after the termination of labor. An analysis of a large number of cases proves that post-partum fever is more common in these cases and removal of the stitches will often be followed by a rapid fall of temperature. Waiting twenty-four hours is still worse since the lochia are more infectious and the patient is disturbed in her much-needed rest. It is not commonly known that the functional results are excellent in 77 per cent. of the cases where healing is left solely to nature. Sometimes the wound-edges are not accurately opposed, leading to slight distortion which does not interfere in any way. Suturing may, however, be done where the wound is simple and without contusion or infiltration, where the general condition is good and strict asepsis can be practiced. In other cases it is better to wait three months.

Pernicious Vomiting.—This is fortunately a rare complication of pregnancy, says Robert Jardine (Brit. Jour. of Obstet., Oct., 1903). Many theories as to the causation of pernicious vomiting of pregnancy have

been propounded, but the etiology of the condition is still very obscure. The displacement theory of Graily Hewett has never recommended itself to the author. Many cases of displacement of the uterus have come under the author's observation where there had never been the slightest vomiting during the whole of the period of the pregnancy. The author is becoming more and more convinced that the true cause is a toxic one, and the poison, whatever it is, acts through the nervous system. The cause surely lies in the uterine contents as the sickness disappears as soon as the uterus is cleaned out. When once thoroughly understood, the tissue metabolism that occurs during gestation, the etiology of pernicious vomiting and of eclampsia will in all probability be made clear. In the treatment of the condition, medicinal means should have a fair trial. Rectal feeding is certainly of great use. When everything is rejected, rectal feeding should be given for ten days or a fortnight. To relieve the thirst, saline injections, given high up in the bowel, or subcutaneously are of great assistance. If the condition is a toxic one saline injections should be useful. After the stomach has had a thorough rest for a fortnight, small quantities should be tried by the mouth. If this is rejected, one must then seriously consider the advisability of emptying the uterus; to delay until the patient is exhausted, is merely to court disaster.

Native Obstetrical Practice in China.—Obstetrical practice is mainly in the hands of ignorant and dirty midwives and nearly every case one meets in practice has been mismanaged by the attendant. Gynecology is on the other hand, undertaken by the native medical man, who is, according to the European ideas, merely a quack. The Chinese do not require their doctors to qualify or take a degree, and often they are quite illiterate men. It is needless to say, remarks AGNES COUSINS (Brit. Jour. of Obstet., Oct., 1903), that vaginal examinations are never made by the native doctors, and the hopelessness of treatment is further increased by the seclusion of the patient. Diagnosis is often made by the pulse, of which the Chinese aver that there are six at the wrist. The midwives are usually of the very lowest class, so much so that the descendants of a woman engaged in this work are not permitted to take a degree, and are therefore debarred from taking office for three generations. A practice is often handed down from mother to daughter and so on. Ordinary cleanliness is unthought of. Puerperal fever is common. The months of pregnancy are usually reckoned as ten by the Chinese. The mother takes no special care during this time and abortions and miscarriages are very common. They do not retire to bed at such times, consequently the hemorrhage is sometimes alarming. If the patient grows faint with it the friends will put her to bed but prop her up, so that the poor woman is made to sit as nearly upright as possible to prevent the discharge gravitating upward to the heart. Treatment is to give native hemostatic, purgatives, or apply counter-irritation to the abdomen. As labor advances, the patient is usually propped up in a squatting position with the buttocks resting just on the edge of a bed or chair (which are always low), her thighs are supported on the knees of two women sitting on either side, and often her arms rest on their shoulders. A third woman from the rear puts her arms on the patient's abdomen, and with the pains makes pressure downward and backward in an effort to express the child. Meanwhile on the floor, and between the patient's knees, which are widely separated, is a stool and on it a receiving bath, in front of which the midwife kneels. She endeavors to stretch the vagina by inserting her fingers and pulling the walls apart, much in the same way that one dilates the sphincter ani with the thumbs before operating for hemorrhoids. If there is delay at the outlet, native drugs are given to cause relaxation of the perineal structures. Sometimes, however, they apply counter-irritation to the vestibule and clitoris instead of giving drugs. This is done either by selecting a sharp fragment of a broken basin, and using it to scarify the part, or by inserting red hot needles. Very few of the women suffer from varicosity of the veins. Owing to the practice of binding the feet the lower extremities are poorly developed, and probably the blood supply to the parts is small. There are among the midwives and native practitioners those who venture a crude embryotomy. Rupture of the uterus is by no means uncommon, neither is it always fatal. As a rule, as soon as the labor is over the patient lies down in bed, but with the head and shoulders bolstered up very high, this with the idea of quickly draining away the lochia. The patient is given a drink of syrup, often with hard-boiled eggs floating in it—a dreadful decoction, of which all friends and visitors are expected to partake. The women often sit up on the day following delivery.

Abdominal Hysterectomy.—In setting forth the advantages of bisection for removal of the uterus in almost all conditions where total ablation of the uterus is indicated, H. A. KELLY (Brit. Jour. of Obstet., Oct., 1903) gives the following advantages of his method of operating: (1) By shortening the period of enucleation, and so bringing the operation to the point of closing the peritoneal and abdominal wounds; (2) by the newer methods, the great uterine vessels, whose control constitutes the chief step of the operation, are promptly secured, and thus any dangerous hemorrhage avoided; (3) by the removal of the uterus, abundant room is afforded to deal with the adherent tubes and ovaries; (4) abundant light is also shed upon the field of operation, and every step can be followed in all its minuter details; (5) new avenues are opened up for releasing the adherent structures from below, from the front or behind, instead of simply working from above as formerly; (16) it is also possible, with greater precision and security, to pack off the diseased structures, sequestrating them from the general abdominal cavity.

Retroversion in the Gravid Uterus as a Cause of Acute Cystitis.—Instances of backward displacement of the gravid uterus are numerous, and there is seldom any difficulty in dealing with this complication. From a clinical standpoint, M. HANDFIELD-JONES (Brit. Jour. of Obstet., Oct., 1903) holds that the cases one sees in private practice may be divided into two groups: (1) Those cases which are serious and urgent and where symptoms present themselves suddenly and (2) cases in which pressure symptoms, due to incarceration of the growing uterus slowly and gradually manifest themselves. There is comparatively little opportunity of a mistake arising in either diagnosis or treatment in the first class of cases, but in the second group there is a much greater likelihood of complications arising, since the patient may be slow to appreciate the gravity of her symptoms, owing to the gradual way in which they have developed, and secondly, the doctor, may look upon the case with less anxiety, because there has been at no time an alarming onset of symptoms.

Diseases Cured by Stem Pessaries.—Thirty years ago we occasionally used stem pessaries for the cure of retrodisplacements but in the course of time, they were discarded because of the danger in their indiscriminate use. J. H. CARSTENS (Am. Jour. of Obstet., Nov., 1903) believes that there is still a field of usefulness that this instrument can enter with safety. In cases of infantile uteri it has proven to be of use in the stimulation of this organ to greater development. The

theory advanced by the author is, the uterus is stimulated and congestion produced and also that the nutrition of the whole pelvis is thereby benefited. The muscles of the uterus are exercised just as those in any part of the body are by the constant effort of the uterus to expel the pessary. Thus the uterus is enlarged and at the same time, it is straightened and the menstrual flow is permitted to pass out unobstructed from the body of the uterus. The greatest trouble is to keep the pessary in the uterus. And for this the author advises the use of the Chapman pessary, made of hard rubber, which can be easily sterilized by boiling. The author takes his patient to the hospital and prepares her as for any other operation. The pessary is introduced, and the patient is kept in bed for one or two days. Then he allows her to get up and walk around, and in three or four days she can leave the hospital and attend to her usual vocation. No after-treatment is necessary, not even hot douches. The author recommends this plan of treatment in the following kinds of cases: (1) Infantile and poorly developed uteri; (2) amenorrhea; (3) scant or irregular menstruation, as is found in fleshy women; (4) simple cases of retroversion, as is found in young girls; (5) cases of stenosis or tortuous uterine canal; (6) the stem must be worn at least six months. A year or even two years is better. If at any time irritation is produced, the pessary can easily be removed.

THERAPEUTICS.

Use of Atropine in Incarcerated Hernias.—D. HAGEN (Deutsch. Arch. f. klin. Med., Vol. 78, Nos. 5 and 6) has discovered that the physiological activity of atropine will readily explain the efficiency of this drug in incarcerated hernias, if the pathology of these be considered. In every incarceration there is a paresis of the musculature of the intestinal loop, accompanied by a reflex tetanic irritation of the external oblique muscle. Since atropine first stimulates muscles supplied by sympathetic nerves, it will tend to overcome the paresis; its subsequent paralyzing action will then be directed against the tetanus of the abdominal muscle. The author proceeds as follows: Half a cubic centimeter of a 1-1,000 solution of atropine sulphate is injected into the neighborhood of the hernia; if this is effective, the dose is repeated every hour; if not, double the dose is injected and a gentle attempt at taxis is made. After six to eight hours a laparotomy is indicated if vomiting continues, and the pulse and facial expression do not improve. It will be possible to save many patients from operation and the method demands an extensive trial, especially in the aged, where the mortality is unusually high.

Bismutose as an Intestinal Astringent.—The value of this preparation is commented on by P. COHNHEIM (Berl. klin. Woch., Dec. 28, 1903). He has used it in a large number of cases of catarrhal intestinal conditions, and finds that although in chronic cases it does not produce a cure, it effectually relieves the distressing symptoms. It is of particular value in the chronic diarrheas of adults, especially in alcoholics, where he has given it in doses of one-half to an entire teaspoonful three times daily after meals. This should be continued for at least four weeks, together with proper regulation of the diet.

Linseed Poisoning.—The following symptoms were produced in a patient who was a robust man, healthy to all appearances, save for a strangulated hemorrhoid. J. O. HOLLICK (Lancet, Nov. 21, 1903) reports that a hot linseed meal poultice was applied to the part at 3 P.M. At 7 P.M. the patient's mouth and throat felt as though they were lined with velvet, the skin of the hands and feet felt as though they were covered with scales. Anserine appeared all over the body, the color of the skin changing from normal to red or purple. There was a rush of blood to the head, the hearing was affected, and the patient was unable to see well; the heart ran up to 120 a minute, the chest seemed to the patient to be tightly constricted. After three-quarters of an hour of these symptoms an acute attack of diarrhea intervened. The patient vomited a quantity of dark material, although he had taken nothing but milk for forty-eight hours. After this the symptoms gradually passed off. On two previous occasions he had been poisoned by linseed, once after eating 12 of the seeds and again after eating lozenges of linseed and licorice. The ordinary linseed meal is obtained by expressing the oil from the seeds and powdering the remains.

Carbonate of Creosote in Pneumonia.—In the hands of J. A. SCOTT and C. M. MONTGOMERY (Therap. Gaz., Dec. 15, 1903) carbonate of creosote in pneumonia caused no irritability of the stomach and no disturbance of the urine. The degree of toxemia in all cases barring the fatal ones was mild and pseudocrises were common, but bore no relation to the crisis or the mortality. The mortality in 67 cases was 14.9 per cent., which does not corroborate the unusually low figures obtained by others, especially since equally low figures were obtained in the same hospital with other methods of treatment. The study of the clinical effects of carbonate of creosote should be continued, the dosage should be increased and the effect upon the toxemia carefully watched.

Serum Treatment of Arteriosclerosis.—The serum of Trunecek, a solution of various mineral salts in water, has given excellent results in the hands of D. SCHEFFLER (La Méd. Moderne, Dec. 23, 1903). When injected hypodermically or into the muscles, a fall of blood-pressure, amounting to 2 to 7 cm., was generally noticed, though the anatomical lesions of arteriosclerosis were hardly affected, even after prolonged use. The most gratifying results were obtained in the functional and subjective complaints of arteriosclerosis and neurasthenia, such as insomnia, dyspnea, pruritus, vertigo, and neuralgia. In chronic rheumatism, on the other hand, no improvement was noted. Success was also experienced in certain urinary and sexual derangements. Where an amelioration was brought about this was lasting in most cases, and in many even permanent. One cubic centimeter should be injected every day.

Properties of Fluorescing Substances.—If strongly fluorescing substances, such as akredin, eosin and quinine, are allowed to act upon lower organisms in the presence of light, they will manifest strong bactericidal properties. Similarly the action of ferments is inhibited and toxins, such as ricin, will lose their power to agglutinate red blood corpuscles. These phenomena are not observed in the dark or if the rays causing fluorescence are cut off. In order to determine any possible therapeutical value, H. v. TAPPEINER and D. JESIONEK (Münch. med. Woch., Nov. 24, 1903) applied eosin to three cases of epithelioma of the face and then exposed the ulcerations to the sunlight. In two, cicatrization was complete in fifty to sixty days, and in the third, an extremely malignant growth, which had destroyed almost the entire nose, healthy granulations were beginning to form. Equally good results were obtained in lupus, scrofuloderma and syphilitic affections of skin and mucous membranes, such as broad condylomata. The action is most intense where the diseased tissue lies exposed, but sometimes the action of light will set up an erythema which hastens ulceration and thus allows the eosin to act directly. Experiments on subcutaneous and oral use of eosin are in progress.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SURGICAL TREATMENT OF SPLENIC DISEASES.

ACUTE hemorrhage from the stomach suggests the existence of gastric ulcer. In a large percentage of cases this supposition is substantiated by operation or by autopsy. In a very small proportion, however, it has been shown that the bleeding had been secondary to disease of the spleen.

To this latter class of cases Banti has given particular attention and writers have coupled his name with the train of symptoms which he has described. Others have preferred to call the disorder "primitive splenomegaly associated with hepatic cirrhosis."

In addition to these terms, several others have been employed in naming esoteric splenic diseases. Banti himself has applied to the special class of symptoms which he has isolated, the term "splenic anemia." Gaucher refers to the same malady as "idiopathic hypertrophy of the spleen;" De Bove as "hypertrophy of the spleen without leucemia." Osler states that "the question of the existence of a separate malady—'anemia splenica'—is still in what might be called the inquisition or tentative stage." Sippy speaks of the condition as "splenic pseudoleucemia." In fine, Douglas laments that the subject is "befogged with a manifold nomenclature."

Fog certainly does exist and an exact nomenclature is a desideratum. The multiplicity of names employed for this simple series of symptoms does, however, show one thing with great clearness: it is that there is great activity in the study of splenic lesions. And yet, notwithstanding this activity, confessedly little is known about such lesions save that if left alone they kill. The hope of the mystified practitioner must be that shortly out of this pathological chaos a therapeutic cosmos will be evolved so that cases shall be brought within the reach of remedy, which now progress not alone untreated but actually unrecognized to a fatal end.

This goal is, however, by no means in sight; the knowledge necessary to attain it is not yet in our possession. How very little, for example, is known of this so-called "Banti's disease" this "symptom complex" which is one of the very important esolienic lesions. While it is possible that the characteristic symptoms—the anemia, the gastric and enteric hemorrhages, the hepatic and splenic enlargements, may be correctly traced to some form of toxemia, or, perhaps, as Barr has suggested, to a vasomotor paresis of the splanchnic area, the fact remains that the etiology of the disease is unknown. Until adequate light shall replace this darkness so that we have definite understanding of the nature of the disorder, it is obvious that no revolutionary medical agent can be suggested. We must, for the time being, depend on the surgical methods hitherto adopted, crude and empirical though they may be.

The surgery of the spleen occupies a place approaching in importance that of the pancreas and the gall-bladder. Chas. G. Levison, in an article on "Splenectomy for Banti's Disease," in the November *Annals of Surgery*, states that in the past decade splenic surgery has made great strides. He quotes from Hargen's monograph, which shows that in eighty-four cases of extirpation of the spleen for chronic malaria there were but seven deaths, or less than 8 per cent. The malaria incidentally was not cured. In 131 splenectomies for different causes there were sixteen deaths (12.2 per cent.). Before 1890 the mortality was 42.2 per cent.

Surgeons have evidently gained in cunning and if splenectomy is indicated to save life the mortality rate does not contraindicate resort to the removal of the organ.

The responsibility of early and accurate diagnosis must rest with the general practitioner. Maragliano and Terrille report sixteen cases of

Banti's disease treated by splenectomy with three deaths. In two of the fatal cases there was probably a mistake in diagnosis. The two diseases with which it is most frequently confounded are hepatic cirrhosis with enlarged spleen; hematemesis being present and splenic leucemia. To operate in the latter case is nearly always fatal, Warren reporting forty-three splenectomies resulting in only five recoveries. Here the differential blood-count settles any doubt.

The condition which Banti describes is characterized by ascites, hepatic cirrhosis and splenomegaly. There are three stages. In the first, which lasts from three to ten years, splenomegaly and anemia are present. The second stage is marked by a reduction in the amount of urine and an increase in bile pigments and urates. It persists several months. The third stage is characterized by the development of ascites, which is painless. Death usually occurs within a year of the advent of this symptom.

The blood changes are only fairly characteristic. Levison recapitulates them as follows: Oligocythemia, the average number of red cells being about 3,500,000; oligochromia, the low percentage of hemoglobin is fairly constant and is marked by a low color index. In pernicious anemia the contrary obtains, and leucopenia. This is quite constant. The red cells and the differential count reveal nothing of diagnostic value.

The postoperative conditions of these cases may be interestingly compared with those which follow the removal of a normal spleen. In the latter case the lymph glands enlarge, the bones become tender; there are characteristic blood changes, polyuria, abdominal pain, thirst; elevation of temperature and of pulse. These symptoms, however, are not observed in the case of children. In splenectomy for extensive esolienic lesions, however, no such changes occur. The splenic function has evidently been slowly assumed—as the lienal parenchyma died—by other organs—an interesting side-light on the too little known topic of vicarious organic action.

ECONOMICS AND TYPHOID.

There is a terse paragraph in the last message of Governor Odell to the legislature, which merits more notice than we have seen credited it. The Governor recommends that means be put in the hands of the Commissioner of Health which will enable him to secure a complete record of the water supplies of the State and the conditions which may produce epidemics.

The Governor's words are as follows:

"A complete record of the sources of public water supplies and the possible conditions which may produce epidemics of typhoid fever or other infectious diseases should be secured by the Health Commissioner, and I recommend that an appropriation be granted by the legislature for this purpose."

According to a report from the State Commissioner of Health, there were nearly 25,000 cases of typhoid fever, with a mortality of 1,635 cases, in New York State during 1903. If we take each life sacrificed to the fever to represent $5,000, as is commonly calculated, there was lost last year, through the deaths alone, $8,175,000. Assuming the expense of nursing the 25,000 cases at the low figure of $50 apiece, the cost of the sickness was $1,250,000. If one-fifth of those who were sick were wage earners receiving wages which averaged $1.50 per day, and each patient was incapacitated for work for about six weeks, the total loss of earnings would probably exceed $270,000. Bringing these several items together, the grand total of the cost of typhoid fever to the citizens of New York State is found to have been over $9,695,000.

A railroad wreck, or a conflagration such as the recent theater fire at Chicago, would, if in New York State, have given a stimulus for legislation for the prevention of the recurrence of similar calamities. Yet the results in lives lost and money sacrificed would, in all likelihood, not be comparable with the losses entailed every year to the citizens of this State by reason of typhoid fever.

It is to be hoped that the Governor's reference to the need of a report on typhoid will receive the prompt and generous support of the legislature. Investigations and circulars of typhoid have been issued by many other State boards of health in the past, and the work should be undertaken here in a broad and scientific manner. We shall look with interest for the introduction of a bill in the present legislature, authorizing the expenditure of the means required, and will favor the employment of the most expert skill which the Commissioner can secure in bringing this matter to a successful conclusion. If the work is well and honestly done, it should produce the most beneficial results in New York and have a wide educational influence elsewhere. If not done in the best manner possible, it would better not be undertaken. Experience shows that parsimony in public health work is poor policy.

ALBUMOSES AND PEPTONES.

RECENT researches in the domain of the physiology of digestion have been exceedingly fruitful of results and have brought into existence such a wealth of literature, widely scattered in the various technical journals, that it is somewhat difficult for the busy physician to remain *au courant*. An occasional survey of the most notable achievements may accordingly not be out of place.

According to the doctrine of Kühne, peptic as well as tryptic digestion of the albumins led to the formation first of primary albumoses, which were then transformed into secondary albumoses and these again into peptones. But, while the albumoses of peptic and of tryptic origin were regarded as identical, Kühne differentiated the peptone produced in the stomach—his amphopeptone—from that produced during pancreatic digestion. In the former, two hypothetical groups were still united, of which one—the hemigroup—could be further decomposed by trypsin, while the other—the antigroup—was resistent. Tryptic digestion, according to Kühne, thus led to an antipeptone, which differed from the amphopeptone in the absence of the hemicomplexes. These were supposedly decomposed with the formation of amido-acids.

This doctrine has been more or less modified by recent investigation. Through the Strassburg school especially it has been shown that the number of primary products of peptic digestion is larger than was supposed by Kühne, and that in the earliest stages of digestion already products are formed, alongside of various albumoses, which no longer give the biuret reaction, and which are now commonly spoken of as peptoids. Later, the primary albumoses are transformed into secondary albumoses, of which also several varieties exist. Following this stage of digestion, products are formed which differ from the albumoses in the fact that they cannot be precipitated from their solutions by saturation with ammonium sulphate, either in the presence of an acid or alkali, or with a neutral reaction.

This brings us to Kühne's concept of peptone and his assumption of an essential difference between that formed during gastric digestion as compared with the product of tryptic digestion, and with it to the question of the unity of these products. Kühne himself doubted the unity of antipeptone, and it has now been demonstrated beyond all possibility of error that an amphopeptone and an antipeptone do not exist in the original meaning of the term. These hypothetical substances have been shown to represent mixtures of various fundamental constituents of the original albuminous molecule, which partly gives the biuret reaction. It has been ascertained moreover that these products are the same, no matter whether the decomposition of the original albuminous molecule has been effected by means of pepsin or by trypsin. The essential difference between the two ferments appears to lie in their effect on the velocity of reaction, viz., the varying rapidity with which the ultimate destruction of the albumin is brought about. In this respect trypsin is more active than pepsin.

With the destruction of the original concept of peptone interest has become centered in those final products from which the tissue albumins must again be constructed. These comprise the common mono-amido acids, leucin, alanin, glycocol, amidovalerianic acid, glutaminic and aspartic acid; the diamido acids, arginin, lysin and histidin; the sulphur body cystin; the aromatic amido acids, phenylalanin and tyrosin, etc. They represent various radicles which probably exist in the albuminous molecule preformed and are linked together in more or less complex groups. The combinations of amido acids E. Fischer has termed peptids, and in a most interesting series of experiments he has shown that bodies of this order are formed during proteolytic digestion and occupy a position intermediary between the albumoses and the true end products. Among the products of tryptic digestion in the case of casein, egg-albumin, fibrin, serum globulin, etc., he could thus demonstrate a polypeptid which still contained the various amido-acids, that can be obtained from the albumins in question, and at a time where such acids already existed in the free state. Probably Siegfried's "peptones" also belong to this group, which are manifestly fairly simple bodies, as on further decomposition they only yield a small number of end products.

To sum up, the evidence is now quite conclusive that both during gastric and intestinal digestion the albuminous molecule is completely broken down to its fundamental components and we are forced to the conclusion that the various tissue albumins are formed synthetically from these comparatively simple substances, in a manner quite analogous to the formation of fat and of glycogen. Löwi has shown that it is possible to maintain nitrogenous equilibrium in dogs by feeding with the crystalline cleavage product, the result of pancreatic autolysis, which no longer gives the biuret reaction, and his results have al-

ready been confirmed by others (Henderson and Dean). In this connection it is interesting to note that the first steps toward a synthetic formation of albumoses have yielded very encouraging results. E. Fischer has suggested that the amido-acids probably exist in the albuminous molecule as anhydrides, and united to each other according to the plan: CH—NH—CO, viz., NH—CH—CO—NH. Starting from this assumption he has succeeded in uniting amido-acids with each other to form various dipeptids and tripeptids and theoretically nothing should be in the way of the artificial production of polypeptids, such as they are now assumed to occur in the intact albuminous molecule.

PROFESSOR HALLIBURTON'S LECTURES AND NERVE REGENERATION.

As the result of a foundation by Dr. Christian A. Herter, there is to be every year at the Bellevue Medical School, a series of scientific lectures on some subjects connected with medicine by a distinguished investigator, or teacher from some other medical school in Europe, or this country.

The first of these series of lectures was concluded on Wednesday of the present week and was given by Professor W. D. Halliburton, of the University of London, England.

Professor Halliburton is known as an original investigator in physiology and physiological chemistry and as one whose conservative conclusions are considered worthy of every attention. His lectures have proved of more than usual interest.

Dr. Halliburton's delivery is excellent and he evidently has the precious gift of teaching, which needless to say, not all original investigators share. It is seldom that a body of students has had the opportunity to enjoy an intellectual treat of so high an order as this in which the *utile cum dulce* were mingled so as to create the feeling that perhaps there was, after all, a royal road to the learning of physiology.

One of the most practical of Dr. Halliburton's lectures, was that on nerve regeneration—a subject that can scarcely fail to be of interest to every practitioner of medicine. The matter has been recently investigated by a number of observers, especially Ballance and Purvis Stewart, in England, and in this country by Howell, Huber and Cushing. Ballance and Stewart have taught that cut nerves regenerate not only from the central stump, as Waller originally taught, but also in the periphery. Howell and Huber have found that while in the peripheral portion of a cut nerve some preparation for regeneration may be noticed, the axis cylinder, the essential part of the new nerve regenerated only from the central portion. In confirmation of this Mott and Halliburton found a great activity of neurilemma cells, which, by the Golgi staining, may resemble nerve fibers, but are not true nerve fibers. This conclusion has been confirmed by the studies of Langley and Anderson at the University of Cambridge in England.

In clinical surgical reports there are certain cases which seem to contradict entirely the teaching of the necessity for new growth of nerve fibers, since apparently they point to direct union of severed ends and almost immediate reestablishment of nervous transmission. Cut nerves are sewed together and feeling is noted very soon afterward. In these cases Professor Halliburton is convinced that it is not the physician who is at fault in his investigations, but the patient who, because of an eminently suggestive mood, wrongly interprets the sensations present. As a rule, whatever sensations may be supposed to be present in the region supplied by the cut nerve, they soon pass off and the true restoration of nervous function takes many weeks or even months, but true return of function, both sensory and motor, has followed nerve anastomosis.

This whole subject of nerve regeneration was treated in a masterly fashion and withal with a pleasant teaching manner that made the lecture always a source of unflagging interest. It is evident that Dr. Herter has done an excellent work in thus providing an opportunity for students of Bellevue to hear distinguished medical authorities outside of their own faculty and his example may well be imitated by other members of the profession, or by others who wish to confer a real benefit upon medical education. These lectures are sure to produce a sympathetic appreciation of the literature of important subjects and at the same time broaden the views of medical students which are apt to be narrow enough as the result of being constantly influenced by the opinions of a single set of specialists.

It is not long since a distinguished foreign medical visitor announced that within a few years European medical students would come to America in order to finish their practical medical education. Under the inspiration of medical opportunities, such as these, we can readily realize that the truth of such a prophecy will be seen much sooner than would otherwise be expected.

ECHOES AND NEWS.

NEW YORK.

East Side Physicians Association.—A medical society under the name of the East Side Physicians Association of the City of New York was organized January 15, with meeting rooms at 206 East Broadway, Manhattan.

The new Association will meet every third Friday evening of the month excepting July, August and September. The following officers were elected for 1904: Dr. Ignatz Morway Rottenberg, President; Dr. Maurice J. Burstein, first Vice-President; Dr. Frederic N. Wilson, second Vice-President; Dr. Nathan Friedman, Secretary; Dr. Maurice Caspe, Treasurer; Dr. Sigmund A. Tarlor, Chairman of Ways and Means Committee; Dr. William S. Gottheil, Chairman of Committee on Ethics; Drs. Robert Abrahams, Abram Brothers and Max Landesman, Trustees; Drs. Maurice M. Berger (Chairman), Julius Solow, Waldema Dorfman, Pierre A. Siegelstein and Isidor Ritter, Committee on Admission.

Food Adulteration in New York State.—Charles A. Wieting, Commissioner of Agriculture, in his report to the legislature, says that the work done under the Pure Food Law of 1903 has been confined to collecting and analyzing samples of food products. With a few exceptions the catsups examined were found to contain preservatives and coloring matter. Out of the 17 samples of cream of tartar eight were found to be substitutes. Of the coffees analyzed a few samples were found to contain foreign substances. Of the samples of molasses and syrups it was found that many were composed of sucrose mixed with glucose. Seven of the 12 oils examined were found to be pure oil and five cottonseed oil. The following table, showing the amount of butter and cheese manufactured in the State, is given:

BIENNIAL STATEMENT.

Year.	Butter, lbs.	Cheese, lbs.
1892	19,497,357	130,991,310
1894	23,218,626	115,763,325
1896	21,429,694	87,765,143
1898	30,586,088	105,405,266
1900	39,183,311	126,658,672
1902	49,919,794	123,987,516

The Commissioner says that New York is the leading cheese State, the amount made here being nearly one-half that produced in the United States. The consumption of pure milk is increasing with great rapidity. While in 1884 the milk consumed in the city of New York was 529,954 forty-quart cans, in 1894 it was 1,939,454 cans, and in 1903 it was 1,734,953 cans.

Woman's Place in Medicine.—Woman's position in the medical world was described by Miss M. Carey Thomas, president of Bryn Mawr College, at the fiftieth anniversary celebration of the New York Infirmary for Women and Children, at the Waldorf-Astoria on Saturday evening. Part of the address was as follows:

"Medicine, though closely allied to nursing and requiring for success many of those same qualities that women seem preeminently to possess, is one of the professions into which the influx of men has been phenomenally great during the past fifty years. So much of a physician's education as precedes the medical degree can now be obtained with little difficulty. Until ten years ago, when the Johns Hopkins University opened its co-educational medical school, which afforded women the inestimable privilege of studying under some of the most eminent physicians of the world, women were excluded from all the great medical schools of the East of the United States. It is only a question of time when all medical schools will admit women. In view of the trend of modern opinion and usage, it seems incredible that in the great city of New York no woman can obtain the first two years of a regular medical training without leaving her native city and residing, at great additional expense, in Ithaca, Philadelphia, or Baltimore, or in some other city. In other respects the other great cities of the East are sadly illiberal to women, and New York is one of the most illiberal of all. It seems incredible that in 1853 Dr. Elizabeth Blackwell found it necessary to found the infirmary to provide clinical work and hospital practice for herself and other women physicians, and that fifty years afterward this infirmary and a small women's homeopathic hospital are still practically the only hospitals where women may practice as internes or as visiting or regularly appointed dispensary physicians. In Great Britain, on the contrary, much greater justice is shown to women. Twenty hospitals in London, ten in Glasgow, nine in Manchester, seven in Edinburgh, and five in Dublin are open to them. The condition of affairs in America is all the more difficult to explain because where women patients are, there should women students and women physicians be—and where men patients are women students and women physicians are no more to be objected to than women nurses; and if we must choose between disagreeable alternatives, it is, after all, far less objectionable from every point of view, except from that of tradition and prejudice, for men and women together to study and treat diseased men in hospitals and clinics than as now in most hospitals for men only to study and treat diseased women.

Value of District Nursing in Tuberculosis.—Prof. Walter B. James in a lecture to his class at the College of Physicians and Surgeons on the treatment of tuberculosis in this city, said that to treat a patient in hospital costs about $1 per day or nearly $400 per year. With a slight addition, this sum would pay the salary of a district nurse for the same length of time and would enable her to supervise the home treatment of from three to five hundred patients. At present by removal to a hospital we can only hope to destroy a single focus of the disease and are pretty sure to leave several behind who will contract it sooner or later. By the "visiting" method, however, it is conceivable that one person in four might be saved from infection. This would apply, of course, only to the very poor who are ignorant of the most fundamental hygienic laws.

Lectures by Dr. Halliburton.—The first series of lectures, established by Dr. Christian A. Herter at the University and Bellevue Hospital Medical College has just been completed by Dr. W. D. Halliburton, Professor of Physiology at King's College, London. The lecturer has for some years been President of the Section of Physiology of the British Medical Association. Two years ago he was selected to deliver the Croonian Lectures before the Royal College of Physicians in London. The present course of twelve lectures was devoted to the consideration of the biochemistry of muscle and nerve. The work is largely the result of the author's own discoveries. The lectures were held daily in the Carnegie Laboratory, 338 East Twenty-sixth street, at 4 o'clock.

Books for the Hospitals.—The twenty-ninth annual report of the Hospital Book and Newspaper Society, which is a branch of the State Charities Aid Association, shows the following work done during the year: Total amount of reading matter distributed during the year ending Sept. 30, 1903—Books, 6,095; magazines, 27,220; weekly and illustrated papers, 47,370.

Collected from the society boxes (estimated)—Books, 2,225; magazines, 11,500; papers, 187,000.

Smallpox Still Active in New York State.—The State Health Department issued its weekly bulletin on smallpox, showing that last week new cases have appeared in the following places in this State: The villages of Salamanca and West Salamanca, Cattaraugus County; the city of Plattsburg, Clinton County; the village of Middleport, and the town of Cambria, Niagara County, and the town of Massena, St. Lawrence County. The epidemic which has prevailed extensively in the village of Medina, Orleans County, appears to have subsided.

Death of Dr. Frank Shaw.—At a special meeting of the Medical Board of the Norwegian Hospital, held Jan. 11, 1904, the following resolutions were unanimously adopted: *Whereas*, we, the members of the Medical Board of the Norwegian Hospital, having learned with profound regret of the death of our late associate, Dr. Frank W. Shaw; and

Whereas, Dr. Shaw, by his nobility of character, scientific attainments, and devotion to the sick, endeared himself to us as a man and a physician; be it therefore

Resolved, that we, the members of the staff, fully realize and feel, that by his death, the entire medical profession has sustained a grievous and lasting loss; and furthermore, be it

Resolved, that we tender our sincerest sympathy to his family in their bereavement; and further be it

Resolved, that a copy of these resolutions be sent to the family, and to the medical journals of our city; and be it further

Resolved, that these resolutions be spread in full upon the minutes of this board.

PHILADELPHIA.

Hospital Bequests.—By the will of the late Henry B. Ashmead his estate of $500,000 reverts to the Episcopal Hospital as a memorial to his wife after the death of his widow and daughter. The late Louis C. Vanuxem bequeathed to the Jefferson Hospital, of which he was a trustee, $25,000.

Medical Jurisprudence Society.—At the meeting of this society, held January 18, Dr. D. J. McCarthy read a paper on "The Conducting of Medical Investigation in Medicolegal Cases at Vienna, with Special Reference to Laboratory Work;" W. W. Smithers, Esq., read a paper on "Criminal Law Procedure in Continental Europe." Officers for the ensuing year were elected.

Philadelphia Medical Club.—The annual meeting of the Medical Club of Philadelphia was held at the Bellevue, January 16. The club is eleven years old and has 570 members. The following officers were elected: President, Dr. E. E. Montgomery; first vice-president, Dr. Roland G. Curtin; second vice-president, Dr. Wharton Sinkler; secretary, Dr. J. Gurney Taylor; treasurer, Dr. F. Savary Pearce; member of the Board of Governors, Dr. E. L. Duer; Executive Committee, Dr. Hobart A. Hare, Dr. Ernest Laplace, Dr. William H. Warder, Dr. Alexander McAlister and Dr. Walter L. Pyle. After the election a loving cup was presented by the society to Dr. Guy Hinsdale, the retiring secretary, who leaves in a short time to engage in practice at Hot Springs, Virginia.

Neurological Society.—In celebration of the twentieth anniversary of the organization of the Philadelphia Neurological Society, the following special program has been announced for the meeting to be held January 26, at 8.15 P.M.: "The Metaphysical Conception of Insanity," by Dr. J. Hendrie Lloyd; "The Mental Processes by Which the Rest-Treatment Was Developed," by Dr. S. Weir Mitchell; "The Surgical Operations Applicable in Insanity," by Dr. J. Chalmers DaCosta; "Mystic Medicine," by Dr. F. X. Dercum. All members of the medical profession are invited to attend.

College of Physicians.—At the meeting of the Section on Medicine, January 11, was held a symposium on "The Early Manifestations of Cirrhosis of the Liver." Dr. W. W. Ford, of Baltimore, spoke on the Pathology; Dr. D. L. Edsall upon the Chemistry, and Dr. Charles G. Stockton, of Buffalo, upon the Clinical Manifestations.

School Inspection.—It is stated that regular inspection of the schools will soon be begun, the additional inspectors to be appointed this week. The experimental inspection of the Mount Vernon school for one month showed that 75 per cent. of the 1,100 pupils were noticeably uncleanly. There were two cases of trachoma, 42 of acute contagious ophthalmia, and 47 of defective vision. Cases of ringworm were also observed. Director Martin, in conjunction with the Board of Education, is arranging a series of lectures on "School Hygiene," for the teachers.

CHICAGO.

To Rebuild Hospital.—The Michael Reese Hospital is to be rebuilt at a cost of more than $250,000. A special committee recently met to provide funds for demolishing the old structure and erecting a new one. The committee decided that to build a suitable edifice at least $250,000 would be required. Of this amount $115,000 was subscribed at the meeting, contingent, however, upon the committee's ability to raise the remainder.

Nurses Must Go Visiting.—Nurses in training schools in the different hospitals of Chicago hereafter will have a month of district or visiting work added to their curriculum. This was decided at a regular bimonthly meeting of the superintendents of hospitals.

New Superintendent for Presbyterian Hospital.—After February 1 the Presbyterian Hospital will have a new superintendent in the person of Dr. Arthur B. Ancker, for twenty-one years superintendent of the city and county hospital in St. Paul, Minn. Dr. Ancker is one of the most eminent hospital superintendents in the United States and has made a wonderful record in St. Paul.

Notes on University of Chicago. Suggestions for enlargement of the work of the University of Chicago, involving a probable outlay of nearly $21,000,000 are made by President Harper in his decennial report of the university, recently issued from the University Press. President Harper's plans for the enlargement of the medical department involve: "The addition of three new clinical departments, medicine, surgery, and obstetrics, the erection of new laboratories on Marshall field, opposite the Hull biological laboratories, the provision of a temporary dispensary near the university; the provision at the earliest date possible of five hospitals for medicine, surgery, obstetrics, children's diseases, and contagious diseases, to cost, with endowment, $1,000,000 each; the raising by Rush Medical College of $1,000,000; the completion of the group of buildings, of which the Senn memorial is the first part, cost $350,000; the organization of a school of dentistry and a nurses' training school."

Institution for Treatment of Infectious Disease.—Chicago is to have a new hospital on the South Side, plans now being under consideration for the erection of extensive buildings where the work of the Memorial Institute for Infectious Diseases will be carried on, and

its scope greatly increased. Thus far the work of the institute has been confined to the treatment of scarlet fever cases, the patients being housed through the leasing of beds at the Presbyterian Hospital, and to original laboratory investigation of scarlet fever. Special provision in the shape of an elaborately equipped laboratory will be made at the new hospital for a continuation of such investigation, which will probably be extended to embrace research as to the nature of other infectious diseases.

Work of Progressive Health Club.—Social ostracism for chewers of tobacco, increased fines and penalties for people who expectorate on sidewalks and in public conveyances and a general acceptance of the doctrine that cleanliness and morality are synonymous terms, are aims of this club. The club's basis objects are the investigation and study of hygiene and home sanitation, pure food measures, climatology, bacteriology, the influence of the solar system on human health, and lastly the expectoration nuisance. But now the last has become the first, and all of the society's energies will be bent toward the abolition of a habit that, in their opinion, has spread more disease and discomfort in centers of population than any one other. The Health Club proposes that special officers be stationed in street cars and on the main thoroughfares to arrest spitters. It is urged that after a few months of such efforts the death rate would decrease, for the spread of typhoid fever and many other contagious and infectious maladies would thus be lessened, and the public health promoted. A few examples of the punishment of offenders would suffice to bring about a general cessation of the habit, for people would be shamed or frightened into desisting from a practice that endangered not only their reputation for cleanliness and decency, but their freedom as well. The aid of all organizations interested in the promotion of the public health, and of reform bodies generally will be invited. Addresses will be delivered to school children, and the board of education will be asked to take up the subject in some form. Associations of physicians, and individual workers in the cause of hygiene and sanitation will be asked to cooperate. Funds will be raised to further the prosecution of all offenders.

Medical Colleges Debarred.—On January 12, the medical examiners of the Wisconsin board decided not to accept as evidence of ample medical training the diplomas of Harvey Medical College, National Medical University, and Jenner Medical College, all of Chicago. The ground for the action is that the courses of study in these institutions do not come up to the standard adopted as the minimum by the Wisconsin board. Other schools that are deficient are to be removed from the accredited list. The board is also about to prosecute a number of unqualified practitioners in the State.

GENERAL.

American Laryngological Society.—The annual meeting of the Eastern Section of the American Laryngological, Rhinological and Otological Society will be held Saturday, January 30, 1904, at the Young Men's Christian Association Building, corner North Main and Pine streets, Fall River, Mass. The medical profession is cordially invited to attend the meeting.

Kalamazoo Academy of Medicine.—The annual meeting of the Kalamazoo Academy of Medicine was held at the Michigan Asylum for the Insane at Kalamazoo on January 12, 1904. The Academy is a district society having 106 active members and holds monthly meetings. A few years ago Dr. Edwin H. Van Deusen, a member of the Academy, gave the City of Kalamazoo a very fine public library building. In this building is a large assembly hall with anterooms, cloakrooms and toilet adjoining, which is by the terms of the gift set apart in perpetuity for the meeting place of the Academy. At the annual meeting Dr. E. C. Dudley, of Chicago, gave an address on "Perineorrhaphy" and operated on a case in the asylum hospital. Dr. Daniel LaFerte, of Detroit, read a paper on "The Treatment of Some Sequelæ of Hip-joint Disease." The retiring President's address was given by Dr. Herman Ostrander, of the asylum staff. The following officers were elected: President, Dr. L. G. Rhodes, South Haven; First Vice-President, Dr. Paul T. Butler, Alamo; Second Vice-President, Dr. M. P. White, Dowagiac; Censors, Dr. O. F. Burrows, Jr., Plainwell; Dr. E. P. Wilbur, Kalamazoo; Secretary, Dr. Della P. Pierce, Kalamazoo; Treasurer, Dr. O. B. Ranney, Kalamazoo; Librarian, Dr. E. H. Van Deusen, Kalamazoo.

Medical Clerk.—The United States Civil Service Commission announces an examination on February 17 and 18, 1904, to secure eligibles from which to make certification to fill eighteen vacancies in the position of copyist (male), at $900 per annum, in the Bureau of Pensions, and other similar vacancies, as they may occur. The examination will consist of the subjects mentioned herewith: (1) Letter-writing (a letter of not less than 150 words on some subject of general interest, competitors will be permitted to select one of two subjects given); (2) penmanship (the handwriting of the competitor in the subject of copying will be considered with special reference to the elements of legibility, rapidity, neatness, general appearance, etc.); (3) copying (a test consisting of two exercises—the first to be an exact copy of the matter given, and the second to be the writing of a smooth copy of rough-draft manuscript, including correction of all errors of spelling, capitalization, syntax, etc.); (4) anatomy and physiology; (5) diagnosis; (6) general and special pathology; (7) surgery and surgical pathology. Age limits twenty-five to thirty years. Only graduates of recognized medical schools may be examined. This examination is held to establish a register of eligibles with a knowledge of medicine. This examination is open to all citizens of the United States who comply with the requirements. Competitors will be rated without regard to any consideration other than the qualifications shown in their examination papers, and eligibles will be certified strictly in accordance with the civil service law and rules. Persons who desire to compete should at once apply either to the United States Civil Service Commission, Washington, D. C., or to the secretary of the local board of examiners at the places mentioned in the accompanying list, for application Form 1312, which should be properly executed and filed with the Commission at Washington. In applying for this examination the exact title as given at the head of this announcement should be used in the application. Persons who are unable to file their formal applications and who notify the Commission of this fact, either by letter or telegram, with the request that they be permitted to take this examination, will be examined, subject to the subsequent filing of their applications, in complete form, provided their requests are received at the Commission in sufficient time to ship examination papers.

OBITUARY.

Dr. EDMUND S. HANNA, for many years a well-known physician of Pittsburg, died January 17, at his residence, 40 William street, East Orange, N. J. He was stricken with apoplexy last Tuesday and never recovered consciousness. He was born in Steubenville, Ohio, seventy-five years ago, and was graduated from Jefferson Med-

ical College, Philadelphia, in 1850. He began practice in Pittsburg and was surgeon of the Allegheny County Workhouse, the Children's Church Home, the Baltimore and Ohio Railroad, and the Allegheny Valley Railroad for many years. He retired in 1888 and moved to Boston, but took up his residence in East Orange eight years ago. He was a member of McCandless Lodge of Masons and Pittsburg Commandery.

CORRESPONDENCE.

OUR LONDON LETTER.

(From Our Special Correspondent.)

London, Dec. 26, 1903.

RETIREMENT OF A FAMOUS PHYSIOLOGIST—THE OXFORD MEDICAL SCHOOL.

Sir John Burdon-Sanderson, Regius Professor of Physics in the University of Oxford has just resigned his chair. He has exceeded the biblical limit of life by five years and doubtless feels that he has well earned a rest from active life. For more than thirty years he has been recognized as one of the foremost physiologists of Europe. After holding the chair of physiology in University College, London, for several years, he was in 1882 appointed to the Waynflete Professorship of Physiology at Oxford, being the first occupant of the chair which had then been newly founded. There was then little or no provision for the practical teaching of physiology at Oxford and a proposal to expend $50,000 in the erection of a lecture room, a laboratory and working rooms, for the purpose, met with determined opposition on the part of a number of Members of Convocation, a large proportion of whom were country parsons. Burdon-Sanderson was known as a vivisector, and antivivisectionist sentiment was aroused to the point of fury. Professor E. A. Freeman, author of the "History of Norman Conquest," etc., denounced the proposal with all the truculence of the overbearing pedant which he displayed in his criticisms of Froude and of everyone who differed from him about anything. The nonsense which he talked on that occasion is scarcely to be matched even among the utterances of the ignorant folk who air their folly in the newspapers. The measure of his comprehension of the question at issue may be gathered from the following "arguments" put forward in his speech. He would not allow any class of men a monopoly in science. As a historian he claimed to be as much a man of science as any one who operated on live rabbits, but he did not ask to be allowed to illustrate the siege of Jerusalem by a repetition of its massacres, or the Elizabethan festivities at Kenilworth by a bull baiting. He deprecated the establishment in Oxford of a "chamber of horrors." After a tough fight the antivivisectionists were outvoted. But they would not accept defeat, and attempted to turn the flank of the enemy by inducing Convocation not to vote the annual grant required for the lighting, warming and general upkeep of the laboratory. This, too, failed, but the controversy led to the severance of life-long friendships and to John Ruskin's resignation of the Slade Professorship of Art. To Ruskin's mind, says his biographer, vivisection meant not only cruelty to animals but a complete misunderstanding of science and defiance of the moral law. Burdon-Sanderson went quietly on his way heedless of the shrieks and curses of fanaticism, and it is now acknowledged that to him more than to any one else is due the important position which the study of the physical sciences holds at Oxford. In 1895 he succeeded to the Regius Professorship of Medicine which had been held by Sir Henry W. Acland for nearly forty years. Ten years ago he received the highest honor which a scientific man can receive from his brethren in this country by his election to the Presidency of the British Association for the Advancement of Science. He has also taken a leading part in the reorganization of the University of London. Himself a graduate of the University of Edinburgh, he was for some time physician to the Middlesex Hospital and the Brompton Consumption Hospital in London. His tastes and aptitudes, however, inclined him more to scientific research than to medical practice. But he has done some good work in pathology, particularly on inflammation, and in the province of public health. Personally he is a man of singular charm with a fine spiritual face which of itself is a sufficient refutation of the charges of cruelty that are still brought against him by the rabble rout of antivivisectionists. As a teacher he was too far above the head of the average student to be helpful for the passing of ordinary examinations. But on men of higher intelligence he had an inspiring influence which stimulated them to spurn delights and live laborious days in the search for knowledge. Many stories are told of his absence of mind, of which the following may serve as a specimen. His laboratory assistant, who watched over him like a nurse, left him one day standing at a table with a frog on one hand and a sandwich on the other. When he returned he found the Professor still absorbed in thought, apparently studying the sandwich, for the frog had disappeared. The animal was never found, and it is inferred that it formed the luncheon of the Professor. Burdon-Sanderson was made a Baronet in 1899 in recognition of his scientific eminence to the disgust of the antivivisectionists who complain that the sovereign specially delights in honoring vivisectors. In proof of this they point in particular to the peerage bestowed on Lister and the knighthood on Victor Horsley. It certainly is a remarkable testimony to the general good sense of our government that those men should have been selected for titular distinction notwithstanding the well-known fact that the Royal family is strongly opposed to vivisection.

It would be difficult to overestimate Burdon-Sanderson's services to Oxford in the development of opportunities for scientific study and research. Twenty-five years ago an outcry was raised in the medical press about the inadequacy or rather the almost total lack of any provision for the study of medicine at Oxford. It was described by Ray Lankester as the "Lost Medical School:" it was said that "vacuity and annihilation now reigned where once medicine flourished and science found her own." Acland, the Professor of Medicine, was denounced as a dilettante, and Rolleston, the Professor of Anatomy was accused of "occupying himself and his pupils with any variety of collateral subjects provided that they had no relation to human anatomy and physiology and could not be pressed into the service of medicine." That there was a considerable amount of truth in these charges is unquestionable. Owing mainly to the conservatism characteristic of Oxford, which was described by Matthew Arnold, as "the home of lost causes," the efforts of the reforming party were defeated. Doubtless the financial difficulty stood in the way, for it was estimated by Ray Lankester that $100,000 a year would be required to maintain a staff adequate to the requirements of a course of practical medicine, and that $250,000 would have to be sunk in additional buildings. But the main obstacle was Acland's rooted objection to the "flooding of the University with mere medical students, specializing from the date of their matriculation, unaffected by the spirit of the place and with the smallest conceivable touch of humanistic learning." Acland was a typical specimen

of the academic mind as formed in our public schools and universities. He never seemed to be able to get rid of the idea that there was something vulgar about medicine, and his gently patronizing manner always conveyed the impression that he felt it a condescension on his part as a member of an ancient family to have adopted it as a profession. Though no great scholar himself, he wished to keep the sacred groves of Academe unpolluted by those who had, like Shakespeare, small Latin and less Greek. While he reigned, therefore, there was no prospect of the lost medical school being restored to life. Yet Cambridge had shown that an ancient university can under right direction be something more than an institution for competitive exercises in classical and mathematical lore and a finishing school for amateur cricketers. Under the influence of the late Professor G. M. Humphry and Sir Michael Foster it has grown from a negligible quantity into the largest medical school in England. Thanks to Burdon-Sanderson, the Oxford medical school, though still small, is now, as far as the ancillary and fundamental scientific subjects are concerned, the most important in the United Kingdom. The students are a select body who have to graduate in arts as a necessary preliminary to graduation in medicine, and the medical degrees of the University are more highly valued than those of any other school. To those who remember the state of things a quarter of a century ago, when the possession of an Oxford or Cambridge degree was a rarity in the medical profession the change is marvelous. Cambridge graduates are now as plentiful as blackberries, while Oxford doctors are fairly common. One result is a marked rise of the profession in the esteem of the British public which knows that the degrees of the two older universities are costlier than others and values them accordingly.

THE PHYSICIAN IN THE APOCRYPHA.

January 11, 1904.

To the Editor of the MEDICAL NEWS:

DEAR SIR: In the *Churchman* of January 9, 1904, George Foster Peabody calls attention to the appended verses in the Apocrypha bearing upon the physician and the "honor due him."

These assembled verses make an excellent short tract. It would be well if they could have a wide distribution especially among "Christian Scientists," "Faith Healers," etc.:

Honour a physician with the honour due unto him for the uses which ye may have of him: for the Lord hath created him.

For of the most High cometh healing, and he shall receive honour of the king.

The skill of the physician shall lift up his head: and in the sight of great men he shall be in admiration.

The Lord hath created medicines out of the earth: and he that is wise will not abhor them.

Was not the water made sweet with wood, that the virtue thereof might be known?

And he hath given men skill that he might be honored in his marvelous works.

With such doth he heal (men) and taketh away their pains.

Of such doth the apothecary make a confection; and of his works there is no end; and from him is peace over all the earth.

My son, in thy sickness be not negligent: but pray the Lord and he will make thee whole.

Leave off from sin, and order thine hands aright, and cleanse thy heart from all wickedness.

Give a sweet savor, and a memorial of fine flour; and make a fat offering, as not being.

Then give place to the physician, for the Lord hath created him: let him not go from thee, for thou hast need of him.

For they shall also pray unto the Lord, that he would prosper that which they give for ease and remedy to prolong life.—Ecclesiasticus xxxviii, 1-15.

THEODORE DILLER.

SOCIETY PROCEEDINGS.

CHICAGO SURGICAL SOCIETY.

Regular Meeting, held December 7, 1903.

The President, Dr. E. Wyllys Andrews, in the Chair.

Keloid Treated by X-rays.—Dr. Wm. M. Harsha reported three cases. The patient was a young man, eighteen years of age, with a small growth behind the right ear, which had existed for ten years. Five years ago it grew to the size of an ordinary marble. It was excised. In three or four months the tumor was as large as ever, and finally grew to be twice the size it was formerly. Histological examination showed the characteristic formation of keloid. The growth was gradually becoming smaller and smaller under X-ray treatment, so that at present it was only one-sixth of the size it was when treatment was begun.

Pancreatic Cyst.—The second case was one of pancreatic cyst in a man aged twenty-nine years. The cyst had attained the size of a large cocoanut, filling the half of the left side of the abdomen. Fluctuation was distinct; there was no temperature, loss of weight, or other disturbance. Resonance could be made out above and to the left side of the tumor. An incision was made at the site of the scar from a former operation; the cyst wall presented, and was followed upward to find the colon above and over the front of it, extending to the pancreas. One-half gallon of fluid was evacuated. The specimen was a thick, turbid fluid of a reddish-brown color, containing thicker grayish-brown mucoid masses. On standing, it deposited a grayish-brown sediment in abundance. The cyst was drawn up into the opening in the abdomen and incised. The cyst wall was one-eighth of an inch thick. An effort was made to detach the cyst wall proper from the peritoneum, but this was so formidable that the operator was content to stitch the edge of the opening to the parietal peritoneum. A large tube was inserted. This kind of drainage has since been continued. The large cavity of the cyst has gradually diminished in size until the present time. Patient made an uninterrupted recovery.

Actinomycosis of Jaw.—This patient, a man fifty years of age, was referred to him with a probable diagnosis of sarcoma of the jaw. The patient had a swelling of the size of a hen's egg at the angle of the jaw on the right side. Actinomycosis was suspected, operation advised, and performed. Microscopic slides showed the characteristic ray fungus in the pus, but not in the tissue. The patient was entirely well.

Dr. L. L. McArthur narrated a case of pancreatic cyst, and said the treatment which had given the best results, though not the lowest mortality, had been total ablation of the sac.

Dr. Halstead mentioned two cases of pancreatic cyst that had come under his observation. In one case the wall was extremely thin. The cyst was opened and drained. In the other the cyst wall was thick, and the cyst contained possibly two quarts of fluid. It apparently grew from the tail of the pancreas, because when

he removed the cyst a piece of the pancreas came with it. He thought in the majority of cases these cysts could be enucleated, and if care was taken in separating the cyst wall from the retroperitoneal tissues, particularly from the large vessels, like the aorta, there was very little trouble. Both patients made good recoveries.

Dr. A. J. Ochsner stated that in several cases in which keloids had been excised and the condition had gotten worse after excision, the improvement was very marked following the X-ray treatment. In one case the keloid diminished to a very slight thickening. He urged that before removing any keloid now one should treat it thoroughly with the X-ray.

Xanthoma Infantum.—Dr. Louis A. Greensfelder reported a case of xanthoma infantum in a boy, aged ten years. The affection dated back as far as the patient could remember. The only manifestations of the disease were found on the cutaneous surface and the tendons, chiefly the extensor digitorum communis, extentor hallucis longus, and tendo Achilles. On the anterior aspect of the chest was a small pedunculated growth, slightly umbilicated, which is sometimes confused with beginning xanthoma, but this was molluscum contagiosum. The symmetry of the lesions was quite striking. A tumor on the right arm had been removed; a tumor involving the right buttocks was characteristic of xanthoma. There was a tumor of the tendo Achilles on both sides.

Dr. Carl Beck mentioned a case of xanthoma in which he had used electrolysis with satisfactory results.

Conservative Surgery in Crushing Injuries of the Arm.—Dr. Daniel N. Eisendrath reported this case as an example of how one could save a member with perfect primary asepsis and the use of conservative methods. He also reported a case of ulcer of the leg following traumatic thrombophlebitis of the lower extremity.

Penetrating Wounds of the Abdomen.—Dr. M. L. Harris read a paper on this subject, in which he reported 16 cases, with 3 deaths. Case I died from rapid profuse internal hemorrhage before the source of the hemorrhage could be discovered and controlled. It might, therefore, be excluded. Case V might also be excluded, he said, as death was due to shock from injury to both lungs and pleuræ and to the spinal cord. Excluding these two cases, there were 14 remaining, with but one death, with eight perforations involving the sigmoid, small intestine and transverse colon, with death on the third day from peritonitis. While in Case II no injury to any of the viscera was found, still operation was imperative on account of hemorrhage. In Cases IX and X neither injury to the viscera nor extensive hemorrhage was found. It may be claimed that these cases would have recovered without operation, and this is undoubtedly true, but who could have foretold before the abdomen was opened. The operation not only did no harm, but was productive of good, as the bullet which might have given rise to subsequent trouble was removed in each case. But, excluding these cases, there were still 11 cases with perforations and hemorrhage in which operation was absolutely indicated, with but one death. Instead of the usual mortality rate of 60 to 70 per cent. following operation, there were over 90 per cent. recoveries. The reasons for this, according to the author's opinion, are chiefly two: (1) Immediate operation. All cases but one were operated on within three hours or less from the time of the accident. (2) Drainage when the gastro-intestinal tract had been opened. The question of drainage in this class of cases was thoroughly discussed at the meeting of the American Surgical Association in 1902, and the consensus of opinion was in favor of drainage. In conclusion the essayist emphasized the following points: (1) In penetrating wounds of the abdomen there are absolutely no known symptoms which indicate injury to any of the viscera, except those noted above in connection with the urinary tract, stomach, and occasionally the lower bowel. (2) Except those relating to general shock, all symptoms following such wounds indicate either internal hemorrhage or peritonitis. (3) To wait for symptoms of perforation of the intestine means to wait until peritonitis has developed; therefore, (4) every bullet or stab wound which penetrates the abdominal cavity should be operated on at the earliest possible moment, in order to anticipate the advent of peritonitis. (5) No time should be wasted in attempting to demonstrate the presence or absence of intestinal perforation by such means as the rectal insufflation of gases or vapors, or the analysis of recollected intraperitoneally injected air or liquids. (6) It is essential to examine systematically the entire gastro-intestinal canal in all cases, regardless of the point of entrance of the wounding body. (7) Whenever the alimentary canal has been perforated, suitable drains should be placed either through the operative incisions or counterincisions, as may appear best suited to the individual case.

Dr. E. J. Seen reported the case of a woman who fell to the ground, striking on the buttocks. This happened about 6 o'clock in the evening, after she had partaken of a hearty meal. She retired without any symptoms seemingly. At 12 o'clock that night she was taken with violent pains in the abdomen. He saw the case the following day in consultation. An operation was advised, consented to and performed. A perforation was found in the lower portion of the jejunum about the size of a small finger-nail. This case showed how there might be a severe injury without immediate symptoms, although he thought the mucous membrane in this case might have protruded in such a way as to have closed off the general peritoneal cavity. He urged early and prompt operation in all cases of perforating wounds of the abdomen.

Dr. Arthur Dean Bevan said he was impressed with reports of the surgeons of the Transvaal war and by the reports of the surgeons during our late war with Spain. He thought these reports could be relied on. In regard to wounds of the stomach, the majority of cases recovered which were not operated upon; a large number of those operated upon died. This statement would not hold good, however, in regard to penetrating wounds of the abdomen in general. There were more recoveries after wounds of the stomach than after intestinal wounds. Where it was possible to do an aseptic operation inside of two or three hours, there could be little doubt that operative treatment should be employed, and he thought the results obtained by Dr. Harris in his cases supported that statement. The conclusions of Dr. Harris, however, should be restricted to civil practice.

Dr. L. L. McArthur thought emphasis should be placed upon prompt interference under such ideal conditions as would obtain in hospital practice. In the cases cited by the essayist there was undoubtedly a perfect surgical technic in the way of antisepsis and asepsis, and which was ideally carried out. Dr. Harris had everything at hand and a corps of assistants that rendered it possible for him to invade any part of the abdomen boldly, freely and safely. These conditions, however, did not obtain in many cases. He was not inclined to believe that every case of perforating wound of the gastro-intestinal tract required drainage, but that the decision should be made upon the conditions found.

through the escape of infective material or not, inflammatory reaction in the peritoneum or not. Certainly he thought it should be as safe to close some of these abdomens as to close, for example, the last two perforations he had had, in which the typhoid stools filled the abdomen in each case, and yet washing it out with salt solution and closing the abdomen, both of the patients recovered.

Dr. D. W. Graham thought the essayist had been unusually fortunate in getting his cases early and under favorable circumstances. He thought cases had been lost by not draining, and believed many of the good results obtained by the essayist were due to drainage. Hereafter, in practically all such cases, he thought he would drain.

Dr. S. C. Plummer narrated a case of stab wound of the abdomen which was inflicted about two inches above and to the right of the umbilicus, with a small portion of the omentum protruding through it. The wound was enlarged and through it an exploration was made, but no injury found to any of the viscera. The exposed portion of omentum was ligated off, and the patient made an uneventful recovery. He narrated a second case of bullet wound. This patient died from hemorrhage.

Dr. John E. Owens said that it was his practice in penetrating wounds of the abdomen to follow the principles laid down by the essayist. The mortality was greatest among those cases in which operations had been delayed. In cases that were operated on early, before the advent of peritonitis, the mortality was very much less.

Dr. Harris, in closing the discussion, said his remarks applied entirely to civil practice. However, he thought the subject of the treatment of wounds in military practice was very much confused. Surgeons knew the great disadvantage under which the military surgeon labored, and the difficulty of getting patients early for operation. The secret of success in these cases was early operation.

Dr. James M. Neff exhibited for Dr. John B. Murphy a specimen from a seven months' abdominal gestation, removed thirteen years later.

Polycystic Kidney.—Dr. Arthur Dean Bevan showed a large polycystic kidney. In this case the clinical symptoms were those of pain on the right side in the kidney region. The man had considerable hemorrhage and secondary anemia from it. The usual incision was made and the mass exposed and removed. The patient made an uninterrupted recovery, having regained his health, weight and strength.

Hypernephroma.—The second specimen exhibited was removed from a case of hypernephroma. An interesting feature connected with the case was that part of the mass projected into the pelvis like a polypus projects into the vagina, and was responsible for the free hemorrhage which was encountered in the case, with profound secondary anemia. He had encountered seven or eight cases of hypernephroma, and said that this form of tumor was a common form of malignant tumor of the kidney. Furthermore, the most severe hemorrhages he had ever seen from the kidney had been in cases of hypernephroma.

Hypernephroma.—Dr. S. C. Plummer reported the case of a man, sixty-eight years of age, who, fourteen months before operation, had a very profuse hematuria. There were practically no symptoms. Patient discovered the tumor accidentally one morning, and about this time he was beginning to show symptoms of malnutrition and weakness. The tumor was removed and proved to be a hypernephroma. There were several cysts connected with it.

THE JOHNS HOPKINS HOSPITAL MEDICAL SOCIETY.

Stated Meeting, held December 7, 1903.

Tumor of the Spinal Cord.—Dr. Thomas showed a patient who had been operated on for this affection. The man, aged thirty years, had been admitted to the hospital six weeks previously. Since June, 1901, he had suffered from slight pain in the left forearm, which, by winter, had become severe, and appeared also in the left shoulder when the head was raised or when patient coughed, laughed, sneezed or yawned. For about one year he had slight disability in left leg. He had also noticed some weakness and atrophy of the left hand and an interference with heat and cold sensation in the right leg. On examination atrophy of left hand, pain down left arm, sensory disturbances on the right side, slight stiffness of the left leg, with weakness of the flexor muscles, and exaggerated reflexes on the left side were found. No disturbance of bladder, rectum or sexual organs. The case looked somewhat like syringomyelia, but the long history of pain without motor disturbance pointed to some pressure-cause and tuberculosis, tumor and pacchymeningitis were thought of. X-ray and tuberculin test were negative and operation was performed by Dr. Cushing. The spines and laminæ of four or five vertebræ (those of the sixth or seventh cervical segments) were excised and an intraspinal tumor (fibrosarcoma of the benign type) was found and removed. The cord was uninjured. Patient recovered completely, the motor power is perfect and the sensory disturbances have practically entirely disappeared.

Perineal Zoster.—Dr. Cushing exhibited this case. The patient was operated on last summer for trifacial neuralgia and was doing well when on the fifth day he developed great pain down the back and legs and a little later a perineal herpetic rash. Only one other case of herpes as low as this has been reported and out of Head's 412 cases of zoster there are only 7 sacral. The segmentation of the cord has been studied anatomically (by actual dissection), embryologically, physiologically (by Sherrington's "method of remaining esthesia"), and clinically (by Head's method of mapping out the areas found in zoster cases). None of these, however, give good results in the sacral region, but this case, in which the sixth sacral segment was involved, clears up somewhat the matter of sacral segmentation.

Notes on Hydatid Disease in Australia.—Dr. J. Ramsay, of Launceston, Tasmania, introduced this subject. Australia has relatively more cases of echinococcus disease than any other country, except Iceland, and the disease occurs in all parts of the island. The natural habitat of the disease is the intestinal canal of dogs. Rabbits, kangaroos and oxen are also infected. The feces of dogs are the chief source of infection for man, but many cases follow the drinking of water from "water holes," creeks, etc. The parasites bore through the intestines, pass to liver and portal vein and then find lodgement anywhere (73 per cent. of the American cases occurred in the liver). Huxley divided the parasites into two classes: The ectocyst and the endocyst, and this classification still holds. Within the cyst wall is found hydatid fluid, containing scolices, hooklets, calcium carbonate crystals, daughter- and granddaughter cysts. The cysts may degenerate (with later calcification), suppurate or rupture. The symptoms vary with the site and are due to pressure, rupture and suppuration. The tumor is usually lobulated, fluctuates, and exhibits a peculiar but not constant thrill. Later suppuration occurs with the picture of sepsis. Ascites occurs, but jaundice is rare. Subphrenic cysts give respiratory and circulatory disturbances. Rupture usual-

ly occurs upward, but the cysts may break into the stomach or colon. The picture of septicemia or pyemia is often seen. The disease is hard to tell from other liver conditions, especially carcinoma. The trochar may be inserted for diagnosis, but fluid does not always escape and the procedure is not altogether free from danger.

The lung is affected next in frequency to the liver, the symptoms being pain, cough, dyspnea, small hemoptysis expectoration. Death or cure may follow rupture, which usually takes place into the bronchi. The disease often resembles pulmonary tuberculosis with which, indeed, it may be associated. Hydatid cysts occur also in the peritoneum, bones, diploë, ovary and uterus. They are uncommon in the kidney, thyroid and spine.

Eosinophilia has been observed in some cases, disappearing after operation. Surgical removal of the cysts is the only successful treatment, and the cases so handled usually recover even when the lung is involved.

Intrapelvic Hematoma Following Labor.—Dr. Williams reported this case. The woman, aged thirty years, was on Nov. 7 delivered by forceps of her first child, the placenta coming away normally. Intense pain about rectum occurred soon after and three hours later this had become very severe, symptoms of internal hemorrhage were present, and a tumor of the abdomen reaching to the umbilicus had formed. Laparotomy was done, expected uterine rupture was not found, but a large hematoma, lying between the bladder and symphysis, was cleaned out, and the cavity packed with gauze. The woman recovered, after a subsequent puerperal infection.

Stated Meeting, held December 21, 1903.

Instrument for Timing Coagulation of Blood.—Dr. Boggs reported some experiments done on the coagulation of blood and showed a new instrument for the estimation of coagulation time. In this apparatus a drop or so of blood is placed on the surface of a truncated glass cone. Over the blood a fine current of air is kept blowing, which causes it to rotate as a whole. At the moment of coagulation, however, the rotation of the blood drop which, during the process, has been watched through a microscope, ceases, owing to the formation of fibrin, and thus a sharp reaction is seen at the moment of coagulation. This instrument is based on the principle of the apparatus first proposed by Brodie and Russell, but it is much less complicated and gives relatively constant results. It is also inexpensive. Dr. Boggs' experiments performed during the summer were directed toward demonstrating the possibility of artificially changing the coagulation time in living animals.

With injection of gelatine the results were very inconstant, but most of the animals were entirely unaffected even by tremendous doses. With calcium salts, however, a rapid decrease in the coagulation time occurred quite constantly, and a return to the normal after stoppage of the drug was also usually noted. Injections of gelatine and calcium salts were also tried on blood which had been made pathological by previous injury. The results for gelatine were in this case also negative. The patients studied clinically included cases of gall-bladder disease, scurvy and purpura, and the results were all good when calcium lactate was used. It is necessary in using the instrument shown to have the surface perfectly clean, and to direct it at right angles to the drop when the blood is drawn. The coagulation time is uniformly longer with this instrument than with the Wright's tubes, averaging from four to five minutes. The administration of calcium in one case of jaundice reduced the coagulation time from 13 to 2½ minutes, and good results were also obtained in carcinoma of the bladder, with hematuria.

Limitations of Urinary Diagnosis.—Dr. R. C. Cabot, of Boston, read this paper, in which he said that accuracy must always be relative to one's purpose, and misdirected exactness is a danger of present day students. The wise man knows where to concentrate his accuracy. A large part of the time spent on urinary analysis in relation to kidney conditions is wasted, for, as Councilman says, the urinary examination does not give any sure information as to the type of kidney lesion to be expected. Dr. Cabot reported two cases illustrative of this view. The first patient had before death one-half per cent. of albumin and very large amounts of casts in his urine. He died of spinal meningitis and no lesion was found in either kidney. In the second patient a postoperative partial suppression of urine with edema were the clinical features, and the urine showed, besides a large albumin content, numerous casts, particularly of the waxy variety. At autopsy the kidneys were found absolutely normal. A review of all the cases of nephritis which have come to autopsy at the Massachusetts General Hospital since 1893 shows that 19 have been of the acute glomerular type, five of which (all accompanied by edema), were recognized during life. Of the 17 chronic parenchymatous cases 15 were recognized during life, but in these the clinical picture was quite characteristic, without urinary examination. Of the 37 chronic interstitial cases 14 were correctly diagnosed nephritis, but in only 4 was the type recognized. Concerning the diagnosis of nephritis we may say: (1) Albumin without pus does not necessarily mean inflammation of the kidney; (2) the presence of casts is not diagnostic, for they may be found in normal urine if it is thoroughly centrifugalized; (3) the estimation of solids and urea in the urine without a complete knowledge of the patient's metabolism is misdirected energy; (4) all the information to be obtained by thorough urine examination may be gotten by noting the color, the specific gravity and the amount of a twenty-four-hour specimen.

Dr. Welch, in the discussion, said that the pathologists cannot, of course, construct a clinical history from seeing the kidneys any more than the clinician can prophesy the kidney lesion. The explanation of this lack of concordance is our ignorance of the condition in the kidney on which albumin and casts depend. Cohnheim made the presence of albuminous urine depend on changes in the glomerular epithelium, and these would be difficult to see microscopically. There is, however, no mystery about the fact, which Dr. Cabot brings forth; it is simply that we cannot recognize the changes.

Dr. Emerson said that the Johns Hopkins Hospital reports of nephritis and albuminuria agree in the main with what Dr. Cabot has said. It is not true, however, that a knowledge of the percentage of albumin in urine, without a knowledge of the total amount, is of no value, for it has been shown that a kidney excreting a small percentage of albumin is in better condition than one excreting a large percentage, even if the total amount of albumin in the former urine is larger than in the latter.

Pericarditis with Effusion.—Dr. Thayer reported two cases of this affection. The first was a man aged twenty-five years, who had had a double pleurisy. A few weeks before he was seen by Dr. Thayer he had been attacked by dyspnea, pain over the heart, and a sudden feeling of faintness. When seen his pulse was 150 and there were marked signs of effusion into the pericardium. A needle was inserted and 1,250 c.c. of straw-colored fluid withdrawn, the pulse falling to normal and the symptoms disappearing. Three weeks later the

heart apex was in the fourth interspace 10 cm., from the middle line, and the absolute dulness was normal. Patient later developed tuberculous laryngitis. The second case was a man aged fifty-nine years, who was admitted to the Johns Hopkins Hospital *in extremis*. There was a large pericardial effusion, but no fluid could be obtained by tapping. 1,200 c.c. were removed at the autopsy table from the pericardial sac. There are three dangers in tapping the pericardium—puncture of the pleura, of the heart, or of the mammary vessels. These, however, amount to little, provided the tapping is carefully done. The question as to the best site for tapping has been much discussed. The places usually advised are, as a matter of fact, well fitted for reaching the heart, though usually chosen with the opposite end in view. Possibly the best plan is to tap at the point where the heart sounds cease to be heard, and so get below the effusion from which point good drainage may be possible. Dr. Cabot said that in his experience most pericardial taps were dry taps and that the successful ones had been those done outside the nipple line. Dr. McCrae said that he had had similar experience. Dr. Cole suggested that these cases be treated surgically from the start, and that free incision be made if necessary, so as to avoid danger of missing the fluid.

Dr. Bloodgood showed lantern slides of benign bone cysts, including the only case which has occurred in the Johns Hopkins Hospital.

MEDICAL AND CHIRURGICAL FACULTY OF MARYLAND.

SECTION ON CLINICAL MEDICINE.

Stated Meeting, held Friday, December 4, 1903.

Anchylostomiasis.—The patient was introduced by Dr. A. D. Atkinson. A man, aged thirty-four years, who had traveled a good deal by sea and had come to Baltimore from the West Endies. He was admitted with fever, weakness and shortness of breath. On examination he was pale, with muddy sclerotics and injected eyes. The leucocytes were 11,600. Intracellular malarial parasites were found; but an eosinophilia (which had been suspected from the fresh blood examination, and was confirmed by differential count) led to careful examination of the stools, where eggs of *Anchylostoma* were found. Thymol and magnesia were given and the worms appeared in the stools in abundance. The case is still in the hospital, but has improved so much that eggs can only occasionally be found in the stools. The leucocytes averaged about 12,000 for the first six weeks, and an eosinophilia (5-11 per cent.) has always been present. Extensive poikilocytosis is also to be observed. The literature of anchylostomiasis has been extensive since the publication of Stiles' work, and it is probable that many of the cases have heretofore been called malaria. Stiles defines it as "a specific zoosporadic disease, occurring in dry, sandy regions, and caused by the hookworm." Its synonyms are Egyptian chlorosis, St. Gothard or tunnel anemia (from the fact that it was carried into Germany by workmen from the St. Gothard tunnel), brickmakers' anemia, miners' cachexia and mountain anemia. The chief symptoms are anemia, dyspnea, edema, colicky pains in the abdomen, and malaise. The disease was first fully described in Italy in 1843, but Stiles records its mention by a German clergyman as early as 1782. *Uncinariasis Americana* is, according to Stiles, a distinct species of the family *Strongyloides*. The differential diagnosis between the old and new world forms is made by definite morphological characteristics, the latter having a bipartite dorsal ray, and a dorsal conical tooth projecting into its buccal cavity. The eggs of *Anchylostoma* lodge in the intestinal tract and develop into adults only after escaping in the feces. The embryo has a characteristic bottle-shaped esophagus and lives in water or moist earth. At the fifth day the worm undergoes a second ecdysis, then infects the human being, and, after a third ecdysis, grows into the adult worm, with an esophagus capable of sucking blood. Anemia is always present. Hemoglobin in the various series of reported cases has averaged about 10-20 per cent., red blood cells about 2,000,000, and whites about 6,000. The anemia is not easy to explain. It is not always in proportion to the number of worms present and is probably not due to the sucking of blood by the parasites. Boycott and Haldane say that it is due to a hydremia, just like chlorosis. A toxin acting on blood or blood-organs has also been suggested as the cause, and the pathological liver changes, with the eosinophilia, seem to support this view. The pathology of anchylostomiasis shows itself in fatty kidneys and liver, catarrhal stomach, hemorrhages of ileum and jejunum, reddened and enlarged Peyer's patches, eosinophilic infiltrations in the intestines, and the bone marrow of pernicious anemia. Reddened areas appearing suddenly in the skin (the "bunches" of Cornwall miners) may be present and may lead to the so-called "ground-itch." The treatment consists of the administration of thymol in xx to xxx-grain dosage, followed by a purge, and repeated until the eggs appear in the stools. The prognosis is good in all but young and badly nourished children.

Pathological Specimens.—Dr. W. R. Stokes showed these. The first showed typical tuberculous areas in the epididymis. In this case incision had been made into an epididymitis and pus-containing tubercle bacilli, but no gonococci were found. The second specimen was of a fracture of the first rib. The injury had resulted from the patient's being jammed between two freight cars, and had been associated with a fracture of the clavicle and laceration of the stomach. No other ribs were broken. The specimens of two cases of acute endocarditis were also shown, both affecting the aortic and mitral valves. The last specimen was a cirrhotic liver taken from a patient seen in May, with a large palpable liver and a history of epistaxis. A diagnosis of alcoholic cirrhosis was made. At autopsy the liver showed typical atrophic cirrhosis and the granular kidneys of chronic interstitial nephritis. Several varices were found around the cardiac end of the stomach, which, when squeezed, showed several small punched-out ulcers. The stomach was full of blood and death had evidently been due to leakage from the ulcers below the dilated esophageal veins.

Dr. Blake said in reference to the second specimen shown that fracture of the first rib was very rare, except from bullet wounds or in extensive injuries, and he did not understand the mechanics of the occurrence of this fracture without other lesions.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, held at the New York Academy of Medicine, December 14, 1903.

The President, Andrew H. Smith, M.D., in the Chair.

Water Anesthesia in Operations about the Rectum, Anus and Buttocks.—A paper on this subject was read by Dr. Samuel G. Gant. More than 150 cases of rectal affections radically operated upon by him had shown that sterile water, properly injected, is a reliable anesthetic; and he was convinced that this is the most desirable method for these operations, for the reason that it produces an adequate degree of anesthesia, while

in no instance has its employment been accompanied or followed by any of the annoying and dangerous complications frequently met with under the use of cocaine or similar drugs. He had been induced to try distention of the tissues with water to produce local anesthesia in consequence of the following observations: (1) Cocaine, eucaine and other similar solutions were practically inert when distention was not obtained, because of the escape of the fluid through an ulcer, fissure or sinus; (2) very weak solutions of the same drugs were apparently as effective as strong ones in all cases where complete distention of the tissues was possible. Among the cases in which Dr. Gant has successfully employed water anesthesia are included radical operations for protruding and non-protruding internal hemorrhoids, cutaneous and thrombotic hemorrhoids, polypi, prolapsus ani, fistulæ of various kinds, and marginal and follicular abscesses; excision of perineal cysts, sacral dermoids, and lipomata of the buttocks; removal of foreign bodies beneath the skin and mucosa; division of the sphincter in cases of constipation where divulsion proved ineffective; fixation of an elongated sigmoid to the anterior abdominal wall; colostomy and exploratory laparotomy.

Technic.—The only requirements are sterile water and a hypodermic syringe fitted with a long, fine, sharp-pointed needle, which, with the syringe itself, should be sterilized. When an incision through the skin is required, a fold of the integument at one extremity of the line of incision is compressed for a few seconds between the thumb and forefinger; this diminishes and prevents the momentary pain which may be caused by the first injection. The needle is then introduced between the layers of the skin, and a few drops of water slowly injected; immediately on the appearance of the small, localized swelling thus produced cutaneous anesthesia should occur at this point. Next, the needle is slowly inserted further and further along the line of the cut to be made, care being taken not to go entirely through the skin, and the water is gradually injected as before. When the syringe is emptied, it is refilled and the needle reintroduced within the anesthetized area; the injections being repeated until the distention extends the entire length of the line of incision. The needle is then plunged through this distended line and subcutaneous injections are rapidly made until a firm, whitish, ridge-like swelling, about the thickness of the index finger, is produced. The skin and underlying tissues can now be incised without pain in almost every instance. For external thrombotic hemorrhoids it is requisite to make the injection only between the layers of the skin overlying the clot to be removed, while in excising external cutaneous hemorrhoids both the skin and tumors should be distended tightly. Large internal venous or capillary hemorrhoids may be completely anesthetized within thirty seconds by injecting directly into the center of each tumor sufficient water to distend it tightly and cause it to turn white. Any affection which requires operative procedure to increase the lumen of the anal outlet, or which necessitates incision of the sphincter, may be operated upon under water anesthesia. After the skin and mucous structures up to the anal margin have been distended, injections are made into the mucosa, the submucosa, the external sphincter, and, if necessary, the internal sphincter muscle.

Advantages.—(1) In the majority of rectal operations there is no necessity of requiring the patient to submit to the annoyance and expense of entering a hospital and undergoing general anesthesia. (2) The rapid distention of the tissues to be incised or removed enables the operator to work quickly, and as the patient is not confined to bed during the after treatment, but can come to the office to be dressed, it economizes the surgeon's time and labor. (3) No annoying or dangerous complications or sequelæ have been observed. It eliminates the danger to life from the heart, lung and kidney complications, which may result from the use of ether or chloroform, and it avoids the increased pain and hemorrhage due to straining and vomiting after general anesthesia. (4) Experience has shown that the pain and bleeding following this method are less than when medicinal local anesthetics are employed. (5) The only requirements are a hypodermic syringe, a suitable needle, and boiled water. (6) The radical treatment of hemorrhoids can be so easily carried out in the physician's office, and with so little danger and inconvenience to the patient, that it should regulate to oblivion the vaunted injection treatment, which is so dangerous and uncertain.

Limitations.—This method is not practicable for extensive operations such as are required for excision of the coccyx, the removal of large tumors by excision, or resection of the bowel, or for the relief of complete prolapsus recti, complex, horseshoe, rectovesical, recto-urethral and rectovaginal fistulæ, very extensive abscesses, or strictures, congenital malformations, or other affections located in the upper rectum; neither is it applicable for opening the abdomen in cases where there is a thick layer of fat and the tissues are so loose and flabby that a proper degree of distention cannot be secured.

How it Acts.—As the anesthetization of the part occurs almost instantly upon complete distention of the tissues, it would seem probable that the anæsthesia is produced by the pressure upon the nerves and their endings caused by the distention. If the pressure is too quickly induced, however, by too rapidly injecting the water, it may cause considerable temporary discomfort, amounting to pain in extremely sensitive subjects.

The Puerpera: her Care and Comfort During Convalescence.—This was the title of a paper by Dr. A. Ernest Gallant. Assuming that labor has been conducted on aseptic lines, the perineum guarded or repaired, etc., what, he asked, could be done to prevent the muscular weakness and abdominal distention, with subsequent visceral ptosis, which so often compel women to seek relief? Frequently the patient, when she gets up out of bed, complains for some days of dizziness, vertigo and inability to walk, and some months later she begins to suffer from gastritis, headache and backache, with attacks of nausea, vomiting and pain, the latter usually referred to the right side. On an examination *with her clothing on*, we find a distinct change in the contour of the anterior abdominal wall—flattening from the sternum to the umbilicus and a bulging from that point to the symphysis—which is caused by prolapse (or dilatation) of the stomach, large and small intestine, often the right kidney (rarely the left), the liver and spleen—the enteroptosis of Glenard. In at least 50 per cent. of multiparæ seen by the gynecologist, there is found uterine displacement, due, in the author's opinion, to the dorsal posture while in bed, in consequence of which involution takes place with the uterus resting against the sacrum. In order to illustrate the prophylactic weakness which he advised, Dr. Gallant related a case in his practice. An abdominal binder was very tightly applied and was worn continuously by the patient while in bed and for two weeks following. For the relief of soreness she was given massage (lasting half an hour), and a weak alcohol bath daily for three days, and on the fourth, fifth and sixth day to these were added passive movements of the arms and legs. From the seventh day onward she was directed to raise and lower the trunk and legs alternately, and after getting out of bed to practise light calisthenics. In order to prevent the recurrence of a former uterine displacement she was ordered not to lie on her back, but on the side

or abdomen, and when the uterus had sunk down to the pelvic brim the vagina was filled with sterile gauze, which was changed every forty-eight hours. The tamponing was maintained for two weeks; when a well-fitting pessary was introduced. The patient got out of bed on the tenth day, and was able to walk about with freedom, stating that she felt much stronger than after her first confinement. Before she became pregnant with this second child she had developed a well-marked suprapubic prominence, and she was directed to secure a corset designed especially for the prevention and relief of visceral ptosis, but, owing to her good condition, she neglected to do so until six weeks after getting up, when she expressed herself as much surprised at the degree of comfort, support and improvement in her figure which it afforded her. In connection with the paper Dr. Gallant demonstrated the use of the corset referred to, and presented a specimen of post-partum tubo-ovarian abscess which caused hydronephrosis. The patient made a good recovery after operation.

Dr. Austin Flint, Jr., in discussing the essayist's paper, said that Dr. Gallant was rather radical in his recommendations; at the same time there was much truth in his position. Many accoucheurs, he believed, had observed great benefit from the patient's not lying always on the back, but personally he would not advocate a change of posture as early as Dr. Gallant. The assumption of the abdominal position did not seem to be required before such a time as the uterus could sag over backward. As to the exercise spoken of, he had had no experience, but he would be somewhat timorous about advising it. In the treatment of enteroptosis and movable kidney he objected to the use of a rigid corset, as it tended to prevent a free play of the muscles. He had had patients who got on better without corsets. He would substitute for them suitable exercises, not massage. Speaking of tamponing the vagina, he expressed the opinion that all women should be examined after childbirth a little earlier than was now customary —that is, between the fourth and sixth week, before the uterus becomes small, but after the lochia has entirely ceased and after the uterus has returned to position and regained tone. He was accustomed to employ large glycerin tampons, with either boric acid or tannin. A pessary might or might not be required.

Prevention Rather than Treatment.—Dr. Edward A. Ayers said he felt disposed to consider the means of preventing subinvolution and displacements, rather than their treatment. He believed that one of the most frequent causes of such evils was the incorrect use of the forceps. There are, in fact, very few cases in which the forceps was required, and it was no doubt an error in obstetrical teaching to advocate their too general employment. If the instrument was applied when there was incomplete dilatation of the lower segment of the uterus, and traction was made in such a condition, the practical result was the dragging down of the uterus. Consequently, there was great relaxation and a marked tendency to prolapsus. We should, therefore, be extremely cautious in all such work, and pains should be taken to secure dilatation of the lower uterine segment by the use of the hand before applying the forceps. No fixed rules could be set down, he thought, as regards the general care of the puerpera. In some cases she ought to sit up early, and in others not. A relaxed condition of the abdominal wall might be due to the anemia existing during pregnancy.

How Long Should the Patient be Kept in Bed?—Dr. Eugene Coleman Savidge said that he would respond briefly on one point of the many covered by the paper of the evening, namely, as to how long a woman should be kept in bed after childbirth. His views represented an evolution. When he was interne at the Sloane Maternity the rule was to put the infant in the mother's arms and send her out on the tenth or eleventh day, and, as in the case of all institutional procedure, to the young interne that seemed the proper thing. When he afterward worked in the female out-patient department of Roosevelt Hospital across the street, and got so many of these Sloane cases with retroversion and prolapse, he took the view that three to four weeks in bed after childbirth was the proper rule. He remembered discussing the matter with Dr. Tucker of the Sloane at that time. He believed that now the rule at the Sloane was to keep the patients much longer. When, later, he began studying the relation of muscular relaxation to general enteroptosis, retroversion, prolapse, he reached a conviction that seemed contradictory at first: Too short a period was wrong, and too long a period was wrong. What, then, the alternative? Not to allow a woman to walk about with a subinvoluted womb, and yet not to keep her confined at the expense of the general muscular system. He believed the solution was in permitting an early rising from childbed, say ten days, and then a routine tamponing under the heavy uterus from stopping of the lochia until the time of complete involution, seeing to it that the woman held her tone in the vasomotor and muscular systems. Once tried, the women themselves are the best advocates of this plan. The speaker further said that if "consistency was the foible of the little mind," it was a good characteristic to discard in the face of new light.

Dr. H. P. De Forest said he had understood that the subject to be discussed was the care of the normal puerpera. It had not been his experience that all women required treatment on account of abnormal conditions. In fact, most women seemed to get along pretty well after childbirth. He had studied under two men whom he considered masters in obstetrics, King, of Washington, and Tucker, of New York, and had always tried to follow in their footsteps. He believed that the nearer we approached to nature the better would be the results secured. In normal cases he did not think it necessary to tampon the patient. It was advantageous for the woman, he thought, to assume within a few days other positions than the dorsal, and if she would lie for a considerable portion of the time on the abdomen, the uterus would fall forward. As to pathological conditions, he believed with Dr. Ayers that the high forceps used before sufficient dilatation did as much to cause subsequent trouble as the labor itself; it was necessary, therefore, that we should make a pretty full dilation of the birth course. In order to avoid bad results the woman should be watched and attended very carefully after childbirth, and he was in the habit of furnishing to his patients a complete memorandum of the supplies which might be needed during the puerperium.

Each Case to be Treated According to the Existing Conditions.—Dr. Franklin A. Dorman thought the paper and discussion were not strictly in accordance with the title announced. As to faulty involution, the size of the uterus varied considerably in different instances, and every careful physician should examine the extent of the involution from day to day. Every case should be judged by itself, and it was well to remember that the process of involution depends to some extent on previous pregnancies. If there had been injuries, such as lacerations, it would be very apt to be retarded thereby. He agreed with Dr. Flint that when the uterus had sunk absolutely within the pelvis, and not before, was the time when displacements were to be guarded against. The patient should be allowed to move from side to side, as she felt inclined. The binder seemed to be injurious after the first three or four days, and might tend to produce retroversion.

Two Prophylactic Measures.—Dr. James D. Voorhees spoke of two prophylactic measures against subinvolution. The idea was always in the mind of the accoucheur of letting out the head, if possible, without a nick or laceration of the perineum, while no attention was paid to the *levator ani* muscles. These might be torn, and as nothing was done to remedy the evil, undesirable results might follow. Mucous membrane tears were also apt to be neglected, and these should be carefully repaired. He thought the management of the uterus itself important. The physician should be absolutely sure when he left the case that no clots were left behind in it. In the main he agreed with the ideas of Dr. Gallant, but he had had no experience with the corset.

Patients Should be Cautioned against Over-exertion after Getting Up.—It was important, he thought, that the patient should be cautioned against doing too much, or too soon, after she was up and about. Many physicians were careless in regard to this point, and he had known of various instances in which women had blamed their medical attendants for uterine troubles attributed to the fact that they had been allowed to play golf or take other active exercise too soon.

Dr. Samuel M. Brickner thought injury was likely to result from the use of the binder after the third or fourth day. He had never tried exercises while the patient was still in bed, but he had had some experience with the corset. He desired to call attention to two points: (1) It not infrequently happens that the patient is unable to urinate spontaneously while lying in bed, and as it is manifestly impossible for the physician to be present whenever it is necessary to pass the catheter, this duty devolves upon the nurse. Even the best of our trained nurses are not too conscientious about the disinfection of their hands, and most nurses are prone to be very careless in regard to the matter. In consequence of a somewhat unfortunate experience on this point he now insisted that the nurse should invariably wear gloves when catheterizing the patient. (2) The patient should be permitted to lie on the side very soon, and after six or seven days the abdominal posture should be advised. It should be the constant aim of the accoucheur to restore the puerpera to the sound, normal condition in which she had been before the pregnancy.

Dr. Gallant, in closing the discussion, said that the time to prevent a thing is to prevent it when it begins. The necessity of catheterization may be avoided by permitting the patient to get out of bed to urinate. No trouble will result, and there will then be no danger of cystitis from the catheter or the nurse. As regards Dr. Flint's criticism, he thought means should be adopted early to prevent the uterus from sagging backward, for unless this was done the organ was apt to acquire the habit, so to speak. If we place the patient on the abdomen it is not necessary to tampon so early. As regards the Sloane Maternity patients frequently having to come to the Roosevelt Clinic, as mentioned by Dr. Savidge, he believed that the troubles referred to were not the result of the women getting up too soon, but were due to the fact that they were not in good condition before labor.

The Value of Blood Counts in Very Young Children.—In an article on the practical value of blood counts, W. Gordon (Bristol Med. Chir. Jour., Sept., 1903) notes that in very young children severe anemia may result from trifling causes; that leucocytosis may also result from slight causes, and is apt to be a lymphocytosis; that the spleen is apt to enlarge in any severe anemia; that nucleated red blood cells are more commonly found than in adults; that hereditary syphilis and rickets cause some of the severest anemias.

Stated Meeting, held Thursday, December 17, 1903.

The President, Andrew H. Smith, M.D., in the Chair.

Symposium on the Treatment of Hypertrophy of the Prostate.

When and How Shall We Operate for the Relief of Symptoms Due to Senile Hypertrophy of the Prostate.—Dr. Paul Thorndike, of Boston, read this paper, which will be published in a subsequent issue of the Medical News.

The Best Method of Operating to Effect a Radical Cure of Senile Hypertrophy of the Prostate Gland, Based on a Study of 141 Radical Operations.—Dr. Orville Horwitz, of Philadelphia, read this paper and, from a review of the results obtained, believed the following deductions were justifiable: (1) A routine method is not applicable to the treatment of prostatic hypertrophy; every case is a law unto itself and the treatment will depend on the various conditions presented in each individual case. (2) The dangers attendant on the daily catheterism are greater than those of a radical operation performed at the onset of the symptoms caused by the obstruction. (3) The proper time to perform a radical operation is reached as soon as it becomes necessary for a patient to resort to daily catheterism. (4) The gratifying results obtained by a number of the operations in many cases demonstrates that the Bottini operation is one of great value. It is applicable to a large percentage of cases; which, if properly selected has proved to be the safest and best method of relieving an obstruction caused by prostatic hypertrophy. In those cases in which a stone in the bladder is associated with a prostatic enlargement, litholopaxy may be performed in conjunction with a galvanocautery prostatectomy. (5) A complete prostatectomy is justifiable if performed early before the individual is broken down in health and secondary complications have supervened. In early operation the results are most satisfactory, recovery rapid, and mortality varying between five per cent. and seven per cent. (6) A complete prostatectomy in feeble elderly patients with long-standing obstruction and secondary complication, the prognosis is grave and the mortality ranges between fifteen per cent. and eighteen per cent. If the bladder in these cases happen to be hopelessly disabled, the results obtained by the operation are negative. Cases of this description are only suitable for suprapubic drainage. (7) In ninety per cent. of all cases the gland can readily be removed by means of a median perineal incision. The perineal operation recommended by Bryson is considered the operation of choice. (8) Complete suprapubic prostatectomy is shown to be more dangerous than perineal operation for obvious reasons. A suprapubic prostatectomy is safer if combined with perineal drainage. (9) Partial suprapubic prostatectomy is indicated in such cases as where a valve-like lobe exists which interferes with urination, or where there is a partial hypertrophy of one of the lobes. (10) A perineal prostatectomy is best suited for those cases where the enlargement of a lateral lobe has a tendency to progress towards the rectum, to obstruct the urethra, or project backward into the bladder. (11) A prostatectomy is always attended with more danger than the Bottini operation and the convalescence is more prolonged. In suitable cases the latter operation is therefore the one of choice.

Dr. L. Bolton Bangs said the subject was a very complex one. Any one with much experience with old men would be obliged to make a broad discrimination between classes that were denominated "hospital classes" and those that were well-to-do and intelligent.

In the former, from want of intelligence or opportunity for cleanliness, one was unable to carry out palliative methods and, therefore, something radical in the way of treatment must be chosen. To him the question of operation was not so difficult as to decide when and upon whom to operate. He believed that the primary retention was not a sufficient indication for the radical treatment of the individual. There are men in whom catheter life has been established, who have had more than one attack of retention whose urine shows scarcely any infection, whose residual urine is moderate in amount (five ounces or less), and whose nocturnal urination is rarely over twice, usually once. Such a patient, using the catheter once, twice, possibly three times in the 24 hours, may go on year after year and the residual urine may become reduced from four or five ounces to one ounce, and the patient really improved in all respects by appropriate treatment. A patient had reported at his office that very day who, four or five years ago, had had five ounces of residual urine; he now had only one ounce. He passes his catheter to treat his bladder only once a week and "lest he forget" he passes it every Sunday. If he had not observed such cases before he believed he would have immediately advised some form of radical relief when the patient first consulted him. Therefore, he believed that each case should be studied by itself. These individuals should not be hurried or urged into operation even when the conditions led to a vague fear or dread of trouble in the future. One should see to it that they be kept resolutely and positively under observation in order that the golden moment for operative intervention should not be lost. A careful diagnosis must be made. He did not think that every man with nocturnal frequency of urination, and with a small amount of residual urine, should be considered a subject of organic progressive enlargement of the prostate. Recently in reviewing some cases in the literature he found one patient who had been subjected to prostatectomy, in whom there had been frequent and painful urination, some blood, only *two* drams of residual urine and a stone in the bladder. He said this was not careful diagnosis; if the right deduction had been made and the stone alone removed, he ventured to say that the symptoms would have disappeared and the residual urine with them. Again, he said that many men, particularly among the higher classes, approaching sixty years of age, with habits of high living, abundance of champagne and frequent sexual indulgences, present themselves with a moderate amount of nocturnal frequency and of residual urine; these men need neither catheter life nor radical operation. Here there would be found engorgement of the prostate or prostatitis, and under good hygienic living, with regulation of their habits, particularly as to the use of alcohol, tobacco, coffee, exercise and sexual relations, the residual urine would disappear and there would be no necessity for either the catheter or radical operation. He had had experience with prostatectomy and with the Bottini method and was inclined to agree with Dr. Thorndike that perineal prostatectomy in properly selected cases was the operation of choice. One could not ignore the experiences and results that have been obtained by the Bottini method which certainly was applicable to a certain class of cases. The choice of operation must be determined upon the merits of the case itself. As a result of his experience he believed there was a class of cases which would be greatly relieved and, in some, positively cured, by this method and with a minimum of risk. Regarding the mechanical performance of the operation he said that the Bottini operation required more skill than the operation of prostatectomy. The latter was within both the sight and touch of the operator, and if one stripped back the capsule of the prostate with the rectum as suggested by Murphy, there would be less danger than ever of injuring the rectum. The Bottini method required tactile dexterity and experience in order to do it properly. Regarding subsequent events he did not think enough stress had been laid upon the conditions which might follow these radical operations. He said he had seen patients with a small amount of residual urine who were moderately comfortable with the catheter and others who did not need the catheter. Subsequent to his examination they had been subjected to prostatectomy and been made miserable for life, either by permanent incontinence of urine, by loss of the sexual function or by permanent fistulæ. When we suggest to a patient whatever we deem necessary for his cure or relief, he said, we should bear in mind and tell him the possibilities. He had rarely found permanent incontinence follow the Bottini operation. Thinking over the suggestion made by Dr. Murphy, of Chicago, it is possible that permanent incontinence is due to the fact that the prostatic urethra had been dilated and had formed a secondary pouch into which the urine found its way and from there dribbled. Dr. Murphy suggested that during a perineal prostatectomy a part of the prostatic urethra should be excised and the edges brought together, thus reducing the size of the dilated part.

Dr. Willy Meyer said he had listened with great interest to the most valuable papers presented by the guests. They had covered the ground so thoroughly that he was sure every one in the audience was able, from what he had heard, to form a proper conception of the present status of prostatic surgery. What he thought was expected of those who had been requested to participate in the discussion, was, to state their views on basis of their personal experience in the treatment of this frequent and often so terrible disease of men. He said he was of the opinion that prostatectomy was the most surgical and the most radical operation, in short, that it was the ideal treatment of prostatic enlargement. If it be true, and we know that *it is*, that the trouble of a prostatic was a mechanical one, that the obstruction caused by the gland was doing all the mischief, then it stands to reason that the total removal of such tissue represented the best cure. Thanks to the arduous labors of many of our colleagues the technic of the operation had been perfected to such a point that they were enabled, in most cases, to avoid future complications. The procedure was, therefore, a comparatively safe one. To-day he advised prostatectomy wherever he found no contraindications, and had personally done the operation, by the perineal route, in nine cases; in eight during the last year. He found it the typical and safe operation which his former experience with operations on the prostate by this route, *i.e.*, opening prostatic abscesses on antiseptic principles, removing a tuberculous sequestrum from the prostate, and other operations upon the organ that had become chronically inflamed by gonorrheic infection, had taught him to consider it. As regards the age at which prostatectomy may be safely advised, he had considerably extended the limit, in fact, he believed there was no limit. So long as the patient's *general condition* warranted it, they need not hesitate about advising the operation. In cases where general anesthesia did not seem safe, he used spinal anesthesia, for which latter prostatic surgery he believed furnished a great field, especially in old patients. Its availableness will certainly tend to widen the indication for prostatectomy. In one of his patients, operated upon in November, 1902, spinal anesthesia afforded him ample time for the enucleation of the prostate and the extraction of a large calculus from the bladder. The patient was presented,

cured, before the New York Surgical Society, in January last. In his last case he used Dr. Young's metal retractor and was delighted with it. It was simple and clean, and was of great help to him. It permitted of any amount of traction, enabled the operator to avoid injuring the urethra and ejaculatory ducts and, incidentally, rendered excellent service as a hemostatic, by compression. Still, it must be said that not every prostate could be pulled down by a retractor into the level of the skin wound. He had also always incised the capsule of each lateral lobe by a vertical incision and tried to preserve what Young called the "ejaculatory bridge." Yet, important as he considered this point of keeping absolutely intact the prostatic urethra and important organs at the vesical neck, he did not believe that the preservation of this bridge alone would always determine the future maintenance of erection. Innervation also played a rôle. Further observation would have to determine this point. At all events, prostatectomy must be regarded as the operation of choice. On the other hand, they must give due recognition to the fact that there are cases in which the cutting operation was absolutely refused, or where special circumstances were present, rendering it contraindicated. It was here that Bottini's operation filled its mission. The gentlemen who recognized prostatectomy only, would, in such cases, condemn the patient to the use of the catheter for life, or insist upon the bloody operation, and thus might take the life of patients who might well have been saved by means of Bottini's operation. He had recently tabulated his cases of enlarged prostate treated by Bottini's operation within the last five years (October, 1897, till October, 1902), 59 in number. He was able to trace 34. Of these 28, or 82.4 per cent. were cured or materially benefited; and of fifteen patients who had used the catheter regularly, 10, or 66 per cent., laid the same aside permanently. Of 23 cases that could be utilized with reference to the question of the maintenance of sexual power after Bottini's operation, the power of intercourse was preserved in 20, or 86.9 per cent. It was more or less interfered with in three. Has such an operation not its place in prostatic surgery? Does it deserve to be cast aside as worthless, as is done by so many who have never tried it or perhaps tried it once? He would be sorry if in this progressive country the truth with regard to the value and place of Bottini's operation should not be fully recognized. He was much interested in hearing Drs. Thorndike and Horwitz state their opinions with reference to Bottini's operation in such an impartial way. He said there were two useful methods for helping prostatics, and the profession has no right to speak of prostatotomy *versus* prostatectomy, but ought to say that it has prostatectomy *and* galvanocaustic prostatotomy. For these two methods do not oppose, but complement each other in the radical treatment of the enlarged prostate gland.

Dr. Chetwood said that the history of the surgery of the prostate gland of ten or fifteen years ago described the same operations, generally speaking, as were performed to-day, even the special technic of galvanocauterization. The same questions were under discussion then, but with less knowledge, between suprapubic and perineal operation: and this same discussion had continued ever since. The result of this long-continued discussion of the subject had been beneficial, and there were probably many surgeons to-day and there will be more in future, who would take neither side of this question, and who believed that most of the operations for prostatic hypertrophy had value, and the choice of technic was a question to be decided upon the individual peculiarities of each case. With such ample support as the operations of suprapubic and perineal prostatectomy had, there was no need of any additional testimony in their favor. He said he had particularly to speak of his own predilection for the use of the galvanocautery in prostatic surgery and, in connection with it, adequate vesical drainage. While he had a strong belief in the value of this method, he thought that its use should be combined with an opening into the bladder, not only for drainage, but for examination before and after operation. The Bottini technic had proven satisfactory in a fair number of cases, especially in the hands of such adroit operators as Dr. Willy Meyer and Dr. Young; yet he felt that the great advantage of drainage through an opening into the bladder, and of determining accurately the nature and size of the growth and the result of the incision was superior to any that may be claimed for an operation which avoided incision. He also would raise his voice in opposition to the practice of extirpating the entire prostate gland when only a very small portion of it was at fault in the causation of symptoms, when it had been so frequently demonstrated that the removal of only the portion of the gland which obstructed the bladder outlet was sufficient to bring relief from symptoms. There had occurred undoubtedly unfortunate results due to the too free removal of the prostate during operation, such as recto-urethral fistula, several cases of which he was personally familiar with, and urinary incontinence. It was fair to state that if these complications occurred they were more likely after extensive removal of tissue. He was not committed to the galvanocautery operation by the perineal route, although most of his cases had been done in this manner. A number of cases could be better reached through a suprapubic opening, and the use of the galvanocautery through this route had decided advantages in some instances, notably those with long urethra and deep perineum. He said he had had constructed a special instrument, upon the same lines as his perineal incisor, for use through the suprapubic opening. If the special technic of galvanocauterization, either with or without an opening in the bladder, lessened the danger of operation in any stage of prostatic enlargement and aided in settling the question *when* to operate, it must be given a position of high esteem in prostatic surgery. Personally, he believed that incision into the bladder enhanced the value of galvanocauterization and minimized the danger of operation.

Dr. Hugh H. Young, of Baltimore, said that in pursuance to the request of the chairman he had tabulated his operative cases which he found were now about 150 in number, divided as follows: prostatectomies, 55; Bottini's, 85; castrations, 2; various operations, 8. Castration had been performed twice, under cocaine, in men who were very old and feeble, and in whom the prostate, although very large, did not offer obstruction to urination, but caused severe pain in the rectum, buttocks and thighs by pressure against the nerve trunks situated in the deeper portion of the pelvis. In one case the result was almost magical, the prostate atrophied and the sciatica and other pains, which had been very severe, promptly disappeared. In the other, the prostate proved to be carcinomatous, and there was no result. Of the 85 patients on whom the Bottini operation was performed six died, three as a result of the operation, and three from other causes three to six weeks after the operation. Of those that lived, in two cases no benefit was obtained, in two cases micturition was restored, but the catheter was necessary twice a day on account of a large residual urine. In four cases there was more or less incontinence of urine. Two cases recovered from this after six months. In five cases, with middle lobe enlargement, Dr. Young

operated by a method described by him in 1900, the cautery incision being made obliquely on each side of the median lobe, thus cutting off its blood supply and leading to its rapid atrophy with excellent results. In a number of cases the prostate was of the small sclerotic variety and it was necessary to use the small blade of his modified instrument with multiple blades, but in most cases either blade No. 2 or No. 3 was found the most suitable. As a whole, the results of the Bottini operations were extremely satisfactory, and in a class of patients often very old and weak, the majority being over seventy years, and five were over eighty years of age. Several patients who had used the catheter for from seven to fourteen years gave up its use altogether. In about one-third of the cases calculus was present, and lithopaxy necessary, both operations being done under local cocaine anesthesia. The operation was never done without having previously mapped out with the cystoscope the nature of the intravesical prostatic outgrowths, a procedure which he considered very important in determining the character of the operation, the choice of blades and position and length of the cuts, the presence of calculi, etc. In two cases only was there any serious hemorrhage subsequent to the operation, one came on after six weeks and the other a year later. In the latter case, although the prostate projected into the bladder as two huge intravesical tumors, the result of the operation had been perfect, there being no residual urine present. A perineal prostatectomy was done on account of the hemorrhage. Another case was that of a man seventy-eight years of age who was brought into the hospital with complete retention of urine and in uremic coma. The urine was very foul and contained granular casts and albumin in large amount. He was treated by catheterization, and blood letting, intravenous, subcutaneous and rectal saline infusions, and after being at death's door for a month was finally operated upon by the electrocautery and is now, two years later, well and about town. It is in cases such as the latter that it is doubtful if any other procedure is as safe and sure as the Bottini, and it was not in these cases in which the few failures and fatalities resulted from the operation. But the presence of the occasional failures shows that perineal prostatectomy is the more certain procedure and therefore to be chosen in many cases. The prostatectomy cases were as follows: Sixteen by the suprapubic route with three deaths—only one attributable to the operation. Thirty-six by the perineal route without a death attributable to the operation (one occurring from embolism when the patient was cured and almost ready to leave the hospital not being counted). In three of the perineal cases the combined operation of Alexander had been used, but the suprapubic incision which was deemed necessary to push the prostate down into the perineal wound, so that it could be reached for enucleation below was always objectionable. The rubber balloon tractor of Dr. Parker Sims had been a step in the right direction, the object being to pull the prostate into the perineal wound. Dr. Young had devised a tractor of metal which seems to answer every purpose, and the 33 last perineal prostatectomies had been operated by this instrument, and according to a technic recently published by him.* He believed that we now receive our patients in much better condition than formerly, since practitioners are realizing the importance of curing these cases early and avoiding infection and its train of sequelæ, and he personally had many cases demanding operation in men between forty-five and sixty years, in robust physical and sexual condition, and it had seemed highly advisable to preserve their sexual powers if possible, and by the technic which he practised he was able to preserve in its entirety the prostatic urethra and the ejaculatory ducts in the great majority of cases, as shown by the subsequent presence of spermatozoa on ejaculation. It was not necessary to do an extensive dissecting operation—the central perineal tendon and the small recto-urethralis muscle were the only muscular structures divided and both insignificant. With good retraction of the wound it was not necessary to divide important structures and with his metal tractor drawing the prostate down the entire posterior surface was so close to the skin surface that it was an easy matter to make the incisions so as to leave a median bridge of tissue which contains the ejaculatory ducts and to enucleate the lateral lobes without injury of these or the urethra. After this, if a middle lobe were present, it was an easy matter to rotate the tractor 90 degrees, engage the median lobe and deliver it into the left lateral cavity, where it could be easily enucleated, generally without injuring the vesical mucous membrane covering it. Even in cases with huge intravesical outgrowths of the prostate it was possible to remove them by the perineum. By means of the tractor large projections of the lateral or middle lobes could be caught, drawn downward and enucleated through the perineum. In a recent case, aged eighty-two years, the prostate filled the bladder and presented above the pubes as big as an orange, and the weight was 250 grams. Spinal anesthesia by the method of Morton was used, and had been found so satisfactory in the past three months that he advised its use in all patients in which ether was contra-indicated either from age or other conditions. One-fourth of a grain of dry sterile cocaine dissolved in the spinal fluid in the syringe sufficed for nearly all cases, and made the operation possible in cases where general anesthesia would have been dangerous, as shown by Goodfellow. Bryson's method of making an extravesical suprapubic incision was not longer necessary, since it was possible by means of a perineal tractor to deliver the lobes into the perineal wound. Suprapubic prostatectomy provided poor drainage and had proved more bloody, more in the dark and much longer in convalescence. He believed that very old men who had learned to use the catheter well and were comfortable should not be disturbed. But when a patient presented himself with a healthy bladder and was in fit shape for a radical cure—prostatectomy or Bottini—he could not agree with Dr. Thorndike that such a patient should be given a catheter to use, and that the radical operations should apply only when the catheter had failed. Continued catheterization invariably led to infection, which an early prostatectomy could have prevented, but a late one could never cure. Taken early, perineal prostatectomy was a very benign procedure, and should be performed carefully and conservatively, with due regard to the urethra and the ejaculatory ducts.

Dr. Howard Lilienthal said that his experience in these cases was limited to 19 patients upon whom suprapubic prostatectomy had been performed. Out of the 19 cases he had had but one death, and this patient was uremic at the time of operation. It was his opinion that a technical error had been committed in performing an operation under such circumstances, although the indication was concurred in by very competent counsel. The patient was aphasic, the urine contained a low percentage of urea, there was arteriosclerosis. He considered that he was an extremely bad risk for any kind of an operation. Dr. Lilienthal wished to speak in favor of the suprapubic prostatectomy. Out of 19 operations the patients recovered with perfect function in 18—a very good showing. He thought a

*Journal of the American Medical Association, Oct. 26, 1903.

great deal depended upon the individual who performed the operation, and, with the results he had obtained, he saw no reason for making a change in his method. Among the advantages of the suprapubic route he referred to (1) speed; this he considered a very important factor, especially in old people. It stood to reason that an operation which required but eight minutes was a much safer one than that which required one-half an hour or longer. (2) The incision was made through unimportant structures, through the skin and fascia, the median tendon of the abdomen, and through the bladder. (3) This gave the best opportunity for exploring the interior of the bladder. Sacculation of the bladder with its important prognostic import could be discovered after the suprapubic incision. In three of his cases stone had been found. He had had serious hemorrhages in 2 out of the 19 cases. In one of these he had started to do perineal prostatectomy when a tremendous hemorrhage occurred, similar to those which had on other occasions in this individual, followed faulty catheterization from injury to the bulb. He abandoned that route for the suprapubic one and the patient made a very good recovery. He believed hemorrhages from the bladder itself could be checked by packing the sac which the prostate had occupied. In reviewing his method he stated that with the catheter in the bladder and an atomized bulb attached a median incision through the linea alba was made. The organ was then distended, being pumped full of air. The bladder was then opened with a small puncture with a knife; this opening was stretched with dressing forceps sufficient to admit two fingers. The bladder was then explored thoroughly and carefully and enucleation of the prostate followed in the customary manner, after incising the prostatic mucosa. He said these patients suffered from no shock after this procedure. His patients varied from fifty-two to eighty years of age and all made good recoveries. The most feeble ones he had had out of bed on the third day. He used siphon drainage. As another advantage he said that the bladder by its adhesions to the suprapubic scar drained in such a manner that, even if one did not take out the prostate, the pouch behind the enlarged prostate was rendered more shallow and emptying of the bladder more perfect.

Dr. Alexander B. Johnson said that his own experience in the radical operative treatment of prostatic hypertrophy had been confined to the perineal operation, and his results had been very satisfactory, a large proportion of the cases having survived the operation and being practically cured, the residual urine being very trivial in quantity and his patients suffering from very few of the symptoms of cystitis, perhaps none at all. In each case there had been a marked diminution, or entire abolishment, of the sexual functions. He preferred the perineal route chiefly because he thought that drainage was more easily accomplished and much more satisfactory. As to the question of what proportion of cases coming to surgeons for the relief of symptoms produced by prostatic hypertrophy should be recommended for operation and under what conditions he did not think was a question readily answered in a few words. He believed though that a considerable proportion of the cases of hypertrophy of the prostate occurring in individuals among the more intelligent and comfortable walks of life could be treated very satisfactorily, and for a long time, by means of the catheter. He would not recommend an individual suffering from marked senile degenerations to undergo the perineal or other kinds of prostatectomy. Such cases, he said, were attended by a large mortality rate. But, in those cases which came to him with only a moderate amount of cystitis, with kidneys in fairly good condition, with good lungs and arteries and a good heart, even though they be more than sixty years old, he considered that an operation could be performed with good prospects of relieving the symptoms. He said he had had only a very limited experience with the galvanocautery or the Bottini operation. The experience of his colleagues in the city might prejudice one, so he believed, against it when it first came out.

Dr. Parker Syms said that the radical treatment of prostatic obstruction to urination was undoubtedly the most important question before surgeons to-day. Its operative methods have passed through a complete evolution during the past decade.

He emphasized the dangers of catheter life in this class of patients, and said when they had to resort to the catheter for urination the death rate was practically 100 per cent. His own experience in this line had been quite active during the past few years, and he had operated upon 29 patients. During this period he had also been consulted by a little over 40 patients who had not submitted to operation. To his knowledge more than 50 per cent. of those who refused to submit to operation had died. Among his operated cases he had operated upon 23 without a death, but lost his twenty-fourth case. This patient died apparently from the effect of general anesthesia. The patients who recovered did so without any untoward complications. In regard to the Bottini operation he said he was willing to assume the responsibility of condemning that operation without having had personal experience with it. The Bottini operation was exploited nearly thirty years ago, was thoroughly tested and was universally abandoned because it had proved a failure. Personally he objects to it because it is an unsurgical and unscientific procedure; it is not radically curative, except in a small proportion of cases, and instead of being a safe procedure as claimed by its advocates, it is a dangerous one. Statistics show it to be far more dangerous than perineal prostatectomy. There are three things that he has inveighed against in this connection, one is cystoscopy in these cases of prostatic obstruction, and the other two are the Bottini operation and the suprapubic route for prostatectomy. He likened the suprapubic route to the prostate, to the occipital route to the tonsil. A year and a half ago his friend, Dr. Young, was an advocate of the Bottini method and of suprapubic prostatectomy, and Dr. Young had invited Dr. Syms to visit Baltimore and become a convert to these methods, but he, on the other hand, had promised Dr. Young to visit Baltimore and see Dr. Young performing perineal prostatectomy in preference to the other two methods; he is glad that his prophesy has come true and that Dr. Young is to-day an ardent advocate of perineal prostatectomy. He called attention to the fact that the operation described by Young is practically the one devised by Proust and Albaron, of Paris, they employing almost the same incision and method including the double-bladed tractor. In concluding, he reiterated his opinion that perineal prostatectomy is the safest of all procedures for the relief of prostatic obstruction. In support of this opinion he quoted the statistics of Young, the excellence of whose work is acknowledged by all. Young's cases show about 7 per cent. mortality for the Bottini operation, and nearly 20 per cent. mortality for the suprapubic operation, and practically no mortality for the perineal route.

Dr. Paul Thorndike, of Boston, said that in spite of what had been said in criticism of the catheter, he still claimed for it a place in the treatment of these cases. He hoped the gentlemen realized how large a part in the development of the technic of prostatectomy had

been taken by Dr. Samuel Alexander, of New York City. Eight years ago, he said, when they were all doing suprapubic work, Dr. Alexander began the advocacy of the perineal route, which was then receiving scant attention from the rest of the men in the East, although Dr. Goodbody was having success with it in the West. Since then the perineal route had proved to be the one along which Dr. Thorndike believed that Dr. Alexander's persistent advocacy of this method of operating had played no small part in the rapid development of prostatectomy.

Dr. Orville Horwitz, in closing the discussion, remarked that his paper had embraced most of the questions that had been brought out by the different speakers; and as the hour was late he would occupy but a few minutes in closing the debate. He agreed with Dr. Thorndike that anesthetics were frequently a source of great danger; especially in old and feeble patients. He had found, however, most satisfaction from the administration of chloroform and oxygen given by means of a special apparatus devised for the purpose. He coincided with Dr. Young in the belief that in certain selected cases the application of a spinal anesthesia was the best method to be adopted. He had seen dribbling of urine follow either a Bottini operation or a prostatectomy with the difference that when the condition supervened after the former operation, it is temporary, while in the latter it is usually permanent. Regarding the perineal galvanocautery operation, advocated by Dr. Chetwood, he did not doubt that it might be of service in some special cases; but in 93 operations of the kind performed by him he had never found it necessary to resort to the perineal incision. It is believed that the simple technic recommended by Bryson for performing perineal prostatectomy offered many advantages over other methods, which might be briefly summarized as follows: (1) Only a short time is required in order to remove the gland, which is a great advantage in cases of old people; (2) experience has shown that in 90 per cent. of cases the prostate gland can be safely removed by means of a median perineal incision; (3) no special instruments are required in order to perform the operation; and there is much less danger of the formation of a recto-urethral fistula. It was not believed that a hypertrophied prostate gland can be removed without disturbance of the ejaculatory ducts. The interference with, or removal of the ducts, has no bearing whatever on the production of impotence, as it has been frequently observed that in chronic inflammatory conditions of the posterior urethra the ejaculatory ducts are obliterated; besides, there are many cases on record where there has been a congenital absence of the epididymis and vas deferens, these structures having been frequently resected in diseased conditions giving rise to sterility, but not to impotence. The claim made by the gentleman who advocates the performance of suprapubic prostatectomy, that he had performed the method frequently, and was not familiar with the operation by the perineal route, does not appear as altogether a logical reason for adopting a method which has been found to be much more dangerous and less satisfactory than the removal of the gland by means of the perineum. The surgeon who desires to do the best work must be prepared to select from his experience and knowledge the operation which is best suited for each individual case, and must be able to perform with equal skill and dexterity any of the various manipulations which may be required.

Quarantine for Consumptives in Australia.—The Board of Health of Sydney has decided to treat consumption as an infectious disease and to isolate all cases.

BOOK REVIEWS.

THE AMERICAN POCKET MEDICAL DICTIONARY. Edited by W. A. NEWMAN DORLAND, M.D., Assistant Obstetrician to the Hospital of the University of Pennsylvania. W. B. Saunders & Co., New York, Philadelphia and London.

THIS attractive little volume appears in a new edition in a surprisingly short time after its predecessor. This argues well for its popularity, which appears to be well deserved. Several thousand new words are said to have been added and the work brought fully up to date, but we find that most of the terms announcing the recent investigations on immunity and allied subjects, such as amboceptor, receptor, complement, toxon, precipitin, hemology, etc., are not given, an omission of consequence, since these words are beginning to appear in the literature and their meanings are not apparent to those who see them for the first time.

TRANSACTIONS OF THE AMERICAN PEDIATRIC SOCIETY. Fourteenth Session, held at Boston, May 26, 27, and 28, 1902, with addenda from the Thirteenth Session, and an Index. Vols. I-XIV, inclusive. Edited by WALTER LESTER CARR, M.D. Reprinted from the *Archives of Pediatrics*, 1902.

THIS volume of transactions will prove especially valuable to those interested in this field as it contains an index of the papers read by members of the American Pediatric Society from its first session up to date. The twenty-six essays reprinted are all of interest and deserve attention.

A SURGICAL HANDBOOK; for the Use of Students, Practitioners, House Surgeons and Dressers. By FRANCIS M. CAIRD, M.B., F.R.C.S., and CHARLES W. CATHCART, M.B., F.R.C.S. With numerous illustrations. Twelfth edition. Charles Griffin & Co., Limited, London; W. T. Keener & Co., Chicago.

THIS book has proven itself so useful to the young surgeons of England that it has reached its twelfth edition in about as many years. Even a cursory examination is sufficient to explain its popularity, for it is a model of its kind, compact in form, well printed and illustrated, and replete with information of the practical, every-day sort, not usually occurring in text-books. The principles and methods advocated are all thoroughly modern and reliable, and we take pleasure in bringing it to the notice of all who are not accomplished surgeons.

THE PRACTICE OF MEDICINE. A Text-book for Practitioners and Students, with Special Reference to Diagnosis and Treatment. By JAMES TYSON, M.D., Professor of Medicine in the University of Pennsylvania. Third Edition. P. Blakiston's Son & Co., Philadelphia.

PROFESSOR TYSON'S Text-book of the Practice of Medicine has very deservedly reached its third edition. It is undoubtedly a very useful and thoroughly practical volume. It probably contains more suggestions for treatment than any of the single volume text-books on the practice of medicine published. There are special features that commend it and add greatly to its interest. There are details of the history of the disease so introduced as to throw light on some feature of the affection under consideration that make it very pleasant reading. The chapters on nervous diseases are, we think, the clearest, briefest, most easily understood of any exposition of nervous diseases that we are familiar with in any of the general text-books of medi-

cine. There are many features in the volume that commend it. It lacks much of the technically scientific air that is often so formidable to the student, but appears so necessary to most authors, yet it is thoroughly up-to-date with true modern medical progress. It is very practical and definite in its recommendations for treatment. The chapters on kidney diseases are especially definite as regards diagnosis and treatment and of themselves must commend the book to many readers.

Physical Diagnosis of Diseases of the Chest. By Richard C. Cabot, M.D., Physician to Out-patients, Massachusetts General Hospital; Assistant in Clinical Medicine, Harvard Medical School. Second revised edition. With 147 illustrations. William Wood & Co., New York.

This excellent book well deserves the reputation which it has won among medical students of being the most thorough and reliable work upon the subject which they may conveniently employ. It is not intended to embody any original ideas of the author and is not made confusing to the beginner by the introduction of numerous fanciful and unproven methods of eliciting signs which are urged by certain enthusiasts as furnishing valuable means of obtaining almost pathognomonic evidences of particular conditions. It is founded upon several well-known encyclopedic treatises and endeavors to eliminate the numerous important errors which are found in almost every small and condensed book upon the subject. It is intended for use by the beginner in physical diagnosis, and yet the diseases of the heart and lungs are so thoroughly dealt with that even the most expert diagnostician cannot fail to gain valuable hints and inspiring thoughts from its perusal. It is brought up to date by the addition of a chapter upon radioscopy which is now so frequently used to confirm physical signs otherwise elicited, or to determine conditions which are not yet far enough advanced to enable a diagnosis to be made by other means.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by Dr. H. A. Hare and H. R. M. Landis. Vol. III. September, 1903: Lea Brothers & Co., Philadelphia and New York.

Diseases of the Thorax and its Viscera, including the Heart, Lungs, and Blood-vessels, Dermatology and Syphilis, Diseases of the Nervous System and Obstetrics, make up the list of contents of this last number of Progressive Medicine. The same authors are in control of the same sections, Drs. William Ewart, William S. Gottheil, William G. Spiller and Richard C. Norris, respectively.

A careful reading of the various abstracts here presented confirms and further extends our favorable impression of this work and of its great sphere of usefulness to the practitioner of the country.

While here and there evidences of loose and rapid abstracting are to be found, the work maintains the high standard that is essential in a work of this kind.

Of the various sections, that on the Nervous System fulfills the ideal conditions better than some of the others. Here the author has gone over a wide range of literature and has coordinated many opinions in a general paragraph. He has fairly succeeded in keeping away from the string of isolated abstract style that mars most year books. The author on diseases of the thorax, etc., has not so successfully avoided this slight retrograde tendency.

We note an absence of the subject matter of psychiatry in this volume, in fact, in the five or six years of this series foundation, diseases of the mind have been unaccountably neglected. In view of the fact that they occupy numerically so high a position in the community this oversight is surprising.

In all other respects we find Progressive Medicine of increasing value with each successive edition, and are convinced of not only its temporary value but of its permanent necessity.

A Nurse's Handbook of Obstetrics for Use in Training-Schools. By Joseph Brown Cooke, M.D., Fellow of the New York Obstetrical Society; Lecturer on Obstetrics to the New York City Training-school for Nurses; Surgeon to the New York Maternity Hospital, etc. J. B. Lippincott Company, Philadelphia and London.

Only a few years ago almost all the obstetrical nursing was delegated to those well-meaning but poorly-informed women whose knowledge of the subject was practically limited to their own experiences in becoming the mothers of three or four children. During recent years the attitude of physicians toward this branch of the medical profession has changed considerably so that it is generally recognized that some special training is necessary for one to justly pose as an accoucheur. To properly conduct a labor and subsequent puerperium at the present time according to up-to-date principles one cannot help but appreciate the important rôle which a well-trained nurse plays. The obstetrician is becoming more and more dependent upon her ability to properly care for mother and child and to direct his attention to possible deviations from the normal course of events. To meet the requirements of such a pupil-nurse this volume has been especially prepared. On the one hand, the methods employed to make such works suitable for mothers and nurses, and on the other hand, the deeply scientific teachings intended for the medical student have both been avoided as much as possible and the aim has been to embody "all the science and art of obstetrics that a nurse need know to practise her profession in an intelligent manner, consistent with her position as a scientifically educated woman." We feel that the author has remarkably well attained his object and that the volume deserves a wide use in the nurses' training-schools.

A Text-book of Medicine, Designed for the Use of Students. By James Magoffin French, M.D., Lecturer on Theory and Practice of Medicine, Medical College of Ohio, etc. Illustrated by ten full-page plates and fifty wood-engravings. William Wood & Company, New York.

There is one fault that might be found with this volume. It is too large for a student's handbook and it is not sufficiently complete for the use of a practising physician. The attempt to crowd all the subjects of medicine, including diseases of the nervous system and the various intoxications into the volume has given it a hurried fragmentary air. There are some excellent features in the book. We note, for instance, the charts on which are marked the exact locations throughout the world at which filariasis occurs. Here again, however, there is evidently an effort to prepare the student for examinations, rather than for his practical work, since at least as much space is devoted to the animal parasites of human beings as is given in much larger volumes on the practice of medicine.

We feel sure that when Dr. French will have the opportunity in a subsequent edition to enlarge his volume that it will make an excellent text-book of the practice of medicine. Compression has in our opinion somewhat impaired the value of this edition.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. 84. NEW YORK, SATURDAY, JANUARY 30, 1904. NO. 5.

ORIGINAL ARTICLES.

CRIMINAL PROCEDURE AGAINST THE UNLAWFUL PRACTICE OF MEDICINE.*

BY HON. JULIUS M. MAYER,

OF NEW YORK;

JUSTICE OF THE COURT OF SPECIAL SESSIONS OF THE CITY OF NEW YORK, FIRST DIVISION.

WHAT I shall say to-night will not be set forth in a paper, but in a talk, to some extent, on the subject which has been assigned to me. I shall not endeavor to cover by any means all that may be said on the subject, but, this being a gathering of men supposedly learned, at least in two professions, it is my desire to call your attention to two or three things; for I think that if one tries to cover too much ground, he is liable to lose the force of making a few propositions and points which seem to him salient and important. My only justification for talking on this subject is that, under the law applicable to the courts in this city, the criminal court, known as the Court of Special Sessions, is the court before which, in the main, these cases of unlawful practice of medicine are tried; for that court has jurisdiction of misdemeanors committed in this county, and, as the unlawful practice of medicine is defined by the statute as a misdemeanor, cases arising under that statute come before us.

Now, this statute is peculiar, in that it presents to a court in this State a combined question of fact and of law. In some of the States of the Union the practice of medicine has been defined; but I shall not now refer in detail to the States in which there has been a definition. My friend Mr. Andrews, the very capable and efficient counsel of the County Medical Society, has already written an article upon that subject, in which, among other things, he calls attention to the fact that in this State there is no definition of what constitutes the practice of medicine. Let me read from Section 153, Chapter 661, of the Laws of this State of 1893, as amended in the years 1895, 1896, 1901 and 1902. This is the statute under which our court must act:

"Any person who, not then being lawfully authorized to practice medicine within this State and so registered according to law, shall practice medicine in this State without lawful registration or in violation of any provision of this article; and any person who shall buy, sell or fraudulently obtain any medical diploma, license, record, or registration, or who shall aid or abet such buying, selling or fraudulently obtaining, or who shall practice medicine under cover of any medical diploma, license, record, or registration illegally obtained, or signed, or issued unlawfully or under fraudulent representations or mistake of fact in a material regard, or who, after conviction of a felony, shall attempt to practice medicine, or shall so practice, and any person who shall append the letters M.D. to his or her name, or shall assume or advertise the title of doctor (or any title which shall show or tend to show that the person assuming or advertising the same is a practitioner of any of the branches of medicine) in such a manner as to convey the impression that he or she is a legal practitioner of medicine, or of any of its branches without having legally received the medical degree, or without having received a license which constituted at the time an authority to practice medicine under the laws of this State then in force, shall be guilty of a misdemeanor."

You see at the outset that the gist of the crime is the unlawful practice of medicine, and at once the question arises, "What is the practice of medicine?" and that is a question which we have been compelled to determine as a question of law as well as of fact. In many States, the practice of medicine is specifically defined, and then the only duty of the court is to ascertain whether the defendant charged with the crime has done certain acts which come within that definition; but in this State we must determine whether, as matter of law as well of fact, the defendant has practised medicine.

There was a notion at one time that the practice of medicine, within the statute, involved the prescription of drugs. We have held to the contrary; and we have held, in substance, that the practice of medicine consisted, among other things, in the ascertainment—or the pretended ascertainment—of the malady or disease with which the patient was afflicted; that the diagnosing of the case by a person, whether he prescribed drugs or not, constituted the practice of medicine.

In calling your attention to our holdings in this regard, I am not to be understood as passing beforehand upon some questions which may come before us. It would be manifestly improper for me to anticipate, in respect of certain questions, what we may do if those questions are brought before us. I have, however, brought here the records of two or three cases, which may give you some idea as to what we have decided in our court; and I think I am correct in sayinig that no decision of ours in a case involving the unlawful practice of medicine, has been reversed by any of the higher courts.

I call your attention to the case of the People *vs.* Joseph Rohrer, a brief history of which I will read. The defendant was convicted February 14, 1902, in the Court of Special Sessions.

He advertised as a hydropathic physician and conducted a sanitarium and massage institute at 152 East Eighty-sixth Street, New York. He treated the complaining witness for facial paralysis, applying ordinary hand massage and electrical massage. A demurrer to the complaint was entered by the defendant, and thus the ques-

*Paper read before the Society of Medical Jurisprudence.

tion of law directly arose. Briefs were submitted by the counsel for the County Medical Society and the counsel for the defendant, and the question was argued at length. The trial was strongly contested, and the question, so far as the Court of Special Sessions was concerned, was settled, that the treatment of disease by such a method, whether mechanical or by the use of drugs, if done by a non-registered physician, was in violation of the statute. You will see at once that this case brought up the question whether the prescription of drugs was a necessary ingredient of the crime, and we held that it was not. The case was not appealed, and therefore the decision stands as law.

The case of the People *vs.* Julius A. Ward. This defendant was the head of a school of practitioners known as "somatopathists," otherwise known as a kind of "osteopathists." He occupied apartments at 640 Madison Avenue, New York, where he conducted a school and treated disease by methods other than the giving of drugs. The County Medical Society, as we understand it, undertook in this case to get a decision not on the point that the giving of drugs is necessarily a part of the practice of medicine, but that the treatment of a disease involving, as it did, a diagnosis by a person not duly registered as a physician, was a direct violation of law. In this case the point was not contested before the court, for the reason that the defendant, after being advised by counsel, pleaded guilty, and by his own admission came within the purview of the law.

Then, we have had cases of the so-called "water cure"—"hydropathy" I think they call it. We also had the case of a man who was cured by "nature," whatever that might have been; and in both those cases the court convicted, and the court has not been reversed.

My first suggestion to you, therefore, is this: some time or another there is coming before that court or some other court in this State the question of what is practising medicine; and it seems to me to be the duty of the legislature to define what is meant by the "practice of medicine." I realize that efforts have been made in the legislature to that end. What is the practice of medicine ought not to be a question for a court to pass upon; it should be a concrete expression by the people of the State, through its legislature, in clear, definite form; and the legislature, as representing the sentiment of the people, should state in explicit phraseology what constitutes the practice of medicine; then the courts will be able to apply that definition to such cases as come before them. Thus far the community at large—at least, as I am told—and the medical profession have had no cause to complain of the judicial construction placed upon that question, but I regard the State of New York as behind some of the other States in legislation, in its failure to have the courage to clearly define in the statute what is the practice of medicine, and in leaving the determination of that question, to the courts as a question of law.

The difficulty will arise some day in this shape: In the majority of cases which come before us, some wrong has been done, and the medical societies or the district attorney or some agency prosecuting has had the case called to its attention because of some wrong or injury done to a person who has been treated; but some day or another the question will arise in a case where no actual physical harm has yet resulted; and when that case does arise, involving, as it will, the definition of some new "pathy" or "ism," the question is likely to be an exceedingly important one; and it is a very close question as to just how far the courts can go in ascertaining what is or is not the practice of medicine.

My second suggestion—and I think this is one that may be easily carried out in the coming legislature—is that the law with reference to punishments is seriously defective. Let me read you from this same section 153 the part relating to penalties. After defining what is the misdemeanor, the statute continues:

"and on conviction thereof shall be punished by a fine of not more than two hundred and fifty dollars, or imprisonment for six months for the first offence, and on conviction of any subsequent offence, by a fine of not more than five hundred dollars or imprisonment for not less than one year, or by both fine and imprisonment."

The usual maximum punishment for misdemeanors under the Penal Code of this State is one year, or five hundred dollars fine or both. There are some statutes which provide a different penalty, but that is the general provision as to misdemeanors; and where the law defines the doing or the failure to do an act, as a misdemeanor, and does not fix the punishment, the Code steps in and fixes it at one year's imprisonment, or five hundred dollars fine, or both.

My view is that there should never be, in a case of practising medicine unlawfully, a minimum fine or imprisonment. I do not see why the courts should be limited on a first offence against this statute, to punishing a man for not more than six months imprisonment, or not more than two hundred and fifty dollars fine. The first offence under the present law can be punished only by an imprisonment of six months, or a fine of two hundred and fifty dollars; and you will readily see, as I hope to illustrate, that there have come before the court cases in which the court would have felt it just to impose a very much more substantial punishment than this minimum punishment provided by the statute. The inequality and the absurdity of this limitation perhaps might be realized best when I tell you for illustration that, by a provision of the Sanitary Code, it is in our power to punish a man with imprisonment of one year and five hundred dollars fine for expectoration. But if, perchance, that man should purport to prescribe a medicine which might result in an abortion, and the proceeding was not brought under the particular sec-

tion relating to giving abortion medicine but was brought under this law, we would be restricted to imposing a punishment of six months or two hundred and fifty dollars fine. It has been the experience of the justices of the Court of Special Sessions, that it is always a mistake to provide a minimum punishment. With possibly an exception here and there, there should not be a minimum punishment for crime; and the court always ought to have, within the maximum punishment, the free range and discretion which the peculiar facts and circumstances in any particular case warrant. I would therefore recommend, as an affirmative suggestion to your Society, that this law should be amended so as to make a violation of the statute a misdemeanor punishable in the discretion of the court by not more than one year's imprisonment or five hundred dollars fine or both.

Now, thirdly, I think no man who does not sit in that court—except, of course of counsel for the medical societies—appreciates the difficulties which attend a prosecution to be followed by a conviction which will be sustained, in the cases involving unlawful practice of medicine. The ordinary crimes involving larceny and the crimes against property are, as a broad general proposition, easily discoverable. But when a man or woman is practising medicine unlawfully, he or she surrounds himself or herself with every conceivable safeguard. In the first place, the person who is to be treated, and does allow himself to be treated rarely will turn State's evidence. If you send a detective to a false doctor, the detective has very great difficulty in obtaining any corroboration, because these doctors, so-called, will rarely, if ever, treat a patient or prescribe for him when anybody else is with him. Accordingly, when the case comes to court, a situation is presented where you have the detective's word against the defendant's word; and, as the higher courts again and again have cautioned the lower courts concerning the uncorroborated testimony of paid detectives, you can readily realize that, under the rule which we are bound to obey, namely, that the guilt of a person must be proven beyond a reasonable doubt, it is very difficult for even skilled detectives to obtain the necessary evidence.

The devices that have been presented in cases to us are so numerous and so skilful that it is enough for me to simply refer to them in a general way. A woman goes into one of these places attracted by an advertisement, that she may be relieved of her distress; and the advertiser who pretends to be a doctor will not see that woman unless she be alone, and he will see to it that if there is any person accompanying her, the companion shall be shut off from the interview in such a manner that there will be no chance of corroborating testimony. I might enlarge in this connection upon the difficulty of getting cases which are sufficiently strong to come within the well settled rules of the criminal law in respect of a conviction; it is enough upon this subject that I should simply suggest to you the difficulties.

Now, that being so, I tread upon what some might regard as dangerous ground, but I am not afraid of it. The worst agencies in New York to-day that help the man who sells either real or pretended abortion medicines, the man who sells either real or pretended medicines to cure this or that infirmity relating to the private life of a man or a woman are certain of the New York newspapers; for they make it possible, by their advertisements, to attract the unwary, the superstitious and the fearful. I shall read to you two or three cases of that kind, and that is the reason I have this bundle here (pointing); you need not be afraid of the bundle: I am not going to talk as much as there is in the bundle; but I brought it here, in order that I might quote with accuracy from the court records to show you how dangerous some of these advertisements are.

I do not know much about the technic of journalism, and I assume, from what I read in the newspapers, that the new school of journalism which has been founded by Columbia University is a forward step. I would suggest, if there is a real desire to raise the standard of newspaperism and journalism, that one of the first chairs be a chair on advertising; and let it be taught to the young men who are to be the future newspaper men of the country that the first duty of a great newspaper is to censor its medical advertisements and to see to it that no advertisement shall go into its columns advertising the nostrums of men and women who seek to lead astray unfortunate people, and who usually entrap women who find themselves in a sad position, and who, through their fear or their ignorance, are led on into unhappy situations by following up what these flagrant advertisements say.

You have no idea, I fear, as to the devices which these advertisements set forth so as to attract the unwary. Many of these persons who pose as fortune tellers and palmists, do so simply to cover the giving out of these medicines to which I have referred; and the seriousness of it is apparent when you realize that in some important newspapers in this greater city of ours these advertisements appear, while in the editorials we are commended to the highest moral life. If there are enough newspaper people in this city—and I believe there are—to courageously take up that proposition, and if there are enough men who are not afraid to talk about it, the time must come when such care will be exercised that no advertisement of this kind can be inserted in the newspapers and published by them and thereby lure on these ignorant people. Now let me read one or two of them to you.

Here was the case of Pauline Eulalia, who was found guilty on June 12, 1903, in the Court of Special Sessions for purporting to prescribe certain medicines to a woman. The advertise-

ment itself, in a great New York newspaper, is perfectly innocent—apparently!

CLAIRVOYANT,
PSYCHIC AND PALMIST.
$10.00 READING FOR $1.00.
PRINCESS EULALIA,
Occult Wonder,

Your Life An Open Book To Her.
She Will Tell You What You Called For
—Anything You Want To Know.
Advice That Will Do You Good.
Always Consult the Best.

So positive am I of my powers to tell the past, present and future, and exactly what you want to know, that I will make NO CHARGE! NO CHARGE! unless you obtain perfect satisfaction and find me superior to all other mediums, clairvoyants and palmists in this city.

THE FOLLOWING LIST SHOWS PURELY AND SIMPLY THAT EULALIA HAS BEEN CONSULTED BY THE MOST POPULAR AND MOST NOTED MEN OF THE WORLD, AND HER READING OF THEIR LIVES WAS PRONOUNCED MOST WONDERFUL: President McKinley, President Roosevelt, President Harrison, President Cleveland, Archbishop Ireland, Sen. Chauncey M. Depew, Sen. Mark Hanna, Admiral Geo. Dewey, Admiral Sampson, Emperor of Austria, Emperor of Germany, King of England, Queen Victoria, King of Italy, King of Portugal, King of Servia.

LOVE, COURTSHIP AND MARRIAGE.

Gives truthful revelations on all love affairs, troubles, marriages and by proper advice restores lost affection, reunites the separated, settles lovers' quarrels, tells you when and whom you will marry, and how to win the man or woman you love, and how to make your husband or wife true to you, and how to overpower all your enemies; gives full secret how to control and charm any one you love or meet.

CONCERNING BUSINESS AFFAIRS.

Gives never failing information regarding all kinds of business, financial difficulties, speculation, investments, insurance, changes, travels, health, sickness, love, divorce, marriage, lawsuits, separations, wills, deeds, mortgages, patents, claims, collections, what you are best adapted for.

HOURS: DAILY 10 TO 8, SUNDAY INCLUDED.

Mail $1. Send date of birth, lock of hair, six questions.

102 West 38th St., bet. Broadway and Sixth Av.

This is her prescription:

Dr. Martel's Pills, with the French flag:
3 in morning
5 at noon
7 before dinner
1 white one before retiring
before meals

Thursday afternoon:
2 ounces Creoline, douche three times a day.

Now you see what happens. You can imagine; but let me tell you from our practical experience. An ignorant woman gets hold of that advertisement; she is in trouble; she has not the courage, if you please, to consult with those with whom she should consult. She may be some poor servant girl alone in this country. She goes to this soothsayer or whatever she may be called. She goes upon the theory that she can foretell what is going to happen; and in the course of that conversation the soothsayer says: "Why, you seem troubled." Whereupon the victim says "Yes," and tells her her story. Then she pretends to give her some kind of medicine or another, which has one of two results: if it is a serious medicine, it may create serious physical damage; if it is not, the woman leaves there supposing that certain things can be accomplished—and the first thing you know, she is a suicide; whereas, if she went to a physician of repute, he would advise her as a father, give her encouragement and set her in the honest path.

Now, don't you see that the clientage which that woman gets would be next to impossible, were it not for the fact that there is placed in the hands of the great New York public at a few cents per day a piece of information so easily and so readily, that those who are unwise, ignorant, superstitious or unwary are led astray.

I shall refer now to another case. There was tried before us in April of this year the case of a man named Lewis Reeves, interesting from several standpoints—interesting because a point of law in reference to the first subject I discussed was raised, and interesting on the line of what I am now discussing. I will read you, as it appeared in evidence, the advertisement which was published by a great New York newspaper. This is the advertisement:

ARE YOU UNFORTUNATE? Women desiring to avoid monthly uncertainties and detention from social and other duties should send for EZU, the great French preventive; price $2, and worth it, because it can be depended upon. EZU COMPANY, 247 Sixth Ave., New York.

Counsel for the County Medical Society, Mr. Andrews, placed in evidence the following exhibit. This was not in the newspaper; this was a circular which followed upon the request of a correspondent, and which this man Reeves, otherwise Ezu, sent to his correspondent.

Why They All Do It
247 Sixth Avenue
Room 9
New York.

Why Widows, Maids and Matrons singly and collectively need no longer worry over irregularities is that Ezu effectually routs *any* case, no matter how stubborn or how long standing.

As a Positive Preventative, you don't depend on hope when using Ezu. There's no guesswork about it. It's *sure* as *Fate* and as harmless as dewdrops.

Stop using nauseating pills and drugs that only upset your stomachs. Ezu is a local treatment that eliminates any possibility of danger.

It's not a miracle, but simply an unlooked-for discovery by one of your own sex.

The price is $2.00 a package and money well spent, if you need it. Faithfully yours,
EZU COMPANY.

This man, as Mr. Andrews told me, and as I have had occasion to verify, evidently had gone so far as to take the daily announcements in the newspapers of marriages, and mail this vile circular to every person who he saw by the daily

papers was in the marriage list. As matter of fact, we know of a case where the notice was intercepted by a gentleman whose daughter had just been married and who was then on her wedding tour. The gentleman is a reputable merchant of this community, who was lucky enough to get this circular before it reached those for whom it was intended. Well, Ezu has just completed a term in the penitentiary.

But, you see there were several points in that case which confirm my suggestions to you to-night. In the first place, we should never have been limited to the minimum punishment in that case. In the second place, the publication of that advertisement was almost as criminal as the man himself. And in the third place, there was raised in this case this question, quite ingenious, as you will see: The evidence was that the detective went in and that this man Reeves, otherwise Ezu, asked the woman detective a certain number of questions; and being told by her of certain troubles that she claimed she was suffering under, prescribed this medicine. The counsel for the County Medical Society drew his complaint in such a way that it might have sounded either as a violation against this statute, or as a violation against the statute for giving medicines that were likely to produce an abortion. The defendant asked, and properly so, that the prosecution should elect, and of course, the other crime being a felony, the prosecution elected to try it as for a misdemeanor upon the theory that it was practising medicine unlawfully. Whereupon the defense said: Why, that is not practising medicine unlawfully; this man did not purport to practise medicine; he did not purport to cure anything at all; he purported to do something which, on its face, was not practising medicine; and his counsel moved for a dismissal of the complaint on that ground. Well, that is an argument that is not by any means a foolish argument, as every lawyer here will realize. The court denied his motion, upon the theory that his having examined the woman and purported to have discovered certain conditions and having given her something as a physician involved the unlawful practice of medicine. That case was taken before Judge Lacombe, of the United States Circuit Court, not upon the theory that there was no crime proved but upon the theory of a deprivation of liberty without due process of law, on the ground that the Court of Special Sessions was a court without a jury. Judge Lacombe dismissed his writ. Then he moved for a certificate of reasonable doubt before one of the judges of the Supreme Court, and the motion was denied, without opinion. The case was never taken up, and the man has served his term.

Now, so far as we in the court are concerned, and I believe, so far as the lawyers who make a specialty of these cases are concerned, it would have been a source of great satisfaction to us had that case gone to the Appellate Court, so that we might have a clear and definite opinion upon this subject. In bringing these cases under the statute as for a misdemeanor, you can readily see that some time or other there will be a pretty close question, unless the legislature defines what is meant by the practice of medicine.

There are many more cases I might relate to you and many more advertisements I might read, but let me say here, in conclusion, that I do hope the newspapers of New York will exercise a censorship of their own over their advertisements of this character. The ideal newspaper would be the one which, when it receives an advertisement from a palmist or a fortune teller or a person of some like occupation, would send one of its trusty men to investigate whether as matter of fact the person does legitimately engage in the reading of palms or the telling of fortunes. At present, of course, there is no law against those things. If a person will be gratified by having his palm read, I suppose there is no law that will prevent it; or if a person can foresee what United States Steel is going to do to-morrow by visiting a fortune teller, why I don't suppose that you who have been in Wall Street will have the slightest objection to it; but if there are these fortune-telling and palm reading and similar advertisements, surely the enlightened newspapers of this greater city have a morale which will compel them and each other to live up to the same high standards of conduct which they constantly demand of those of us who are merely laymen and not engaged in the publication of newspapers. Of course, there are a great many exceptions among newspapers which would not think of publishing such advertisements; and I am inclined to believe, from a letter which I have here and which Mr. Andrews has handed to me—from a newspaper man, whose name we are not permitted to mention—that even those newspapers which have been publishing these advertisements, will exercise a censorship, if their attention is strongly called to it and if they can be made to understand the serious difficulties that come from it—and certainly an advertisement so plain, so raw, as this Ezu advertisement doesn't require very much investigation or censorship.

I would read you here, finally—but I cannot lay my hands on it at the moment—the advertisement of a man named Sanford R. Christian, whom we sent to the penitentiary for six months. This was the advertisement of a man under the name of "Dr. and Mrs. Clark"—a long advertisement in one of the important daily papers, showing as nearly as vile phraseology could, that his advertisement was to induce persons to buy the medicines of the character which I have described. That man did a flourishing business, and it took months and months for the medical societies to get after him and finally bring him to the bar of justice. You can readily understand that he would not have done anywhere near that business, if it had not been that he had had the medium of a great newspaper which the people had a right to be-

lieve published honest and decent and trustworthy advertisemtns.

My three suggestions therefore are: first, define the practice of medicine; second, strike out the minimum punishment; and third, devise some method whereby all advertisements of this kind are eliminated from the papers that are published anywhere in the State of New York."

Discussion here followed, participated in by the following named gentlemen: Mr. Champe S. Andrews, Dr. Fischer, Mr. John B. Huber, Dr. Von Ramdohr, Judge Ommen, Mr. Andrews, Mr. Charles M. Demond, Mr. William R. Koehl, Mr. Alexander Campbell, Dr. Sieberg and Mr. Louis J. Vorhaus.

To these remarks Judge Mayer responded as follows:

"I shall refer only to a very few matters which have been suggested during the discussion. There is no doubt that Mr. Vorhaus, the last speaker, has made reference to a practical method —one which has, in fact, been used to some extent. But one of the greatest difficulties, as I think you saw from one of the advertisements I read, is that they bear nothing upon the face that is illegal—like the Eulalia advertisement; there is nothing in that advertisement prima facie illegal or that has any relation to the unlawful practice of medicine. Under the federal statute, I think all the lawyers here will agree that no prosecution will prevail, because not merely as matter of law, but as matter of fact, the character of that woman's business must have been brought home to the publisher or other responsible person

Now, if I have been understood as saying that this evil can be cured by legislation, I failed to express myself clearly. Somebody here in this discussion this evening struck the keynote. My sole purpose to-night was simply to relate some facts which should be called to your attention; but the remedy is a slow one. It will take a long while, but if successful, it will be a permanent remedy—the gradual uplifting of public opinion and of the opinion and conduct of the men, whoever they may be, who are responsible for these publications. Somebody here remarked —I think it was Mr. Demond—that twenty years ago, he used to read very bad advertisements in the newspapers, and that nowadays he doesn't see so many. Well, I think that is true; I think that the columns of the newspapers to-day are ever so much better than they were in this respect; and you and I know of newspapers daily published in the City of New York which do not permit any such advertisements in their advertising columns. There is newspaper after newspaper in this greater city which would not for one moment permit such advertisements. Now, if the men who are responsible for the editing and publishing of those decent newspapers will assist in what seems to all of us the laudable purpose of driving out that class of advertisements from all newspapers, I say that it is simply, as all such matters are, a matter of time and development until this class of advertising will be driven out of the newspapers. As to Mr. Koehl, he was entirely too fearful; these advertisements form only part of the income of some newspapers; doubtless they add comfortably to that income, and yet after all the greatest income of the newspapers is obtained from the legitimate advertisements, those of merchants and others who have legitimate goods to sell, and of persons who advertise public entertainments and the like. I still believe that if the men, most of whom are men of considerable importance, and of excellent character—if the men on these newspapers who are responsible for the publication of these advertisements are so constantly driven at with this single question that I am about to put, the time must come, by the resolutions of societies of this kind, when this thing will be minimized. All you need do is to ask the man who is responsible for those advertisements, if he will please take one of them home to his young daughter and have her read it; and if he says yes, let him publish it, but if he says no, there is some show that you are reaching him in some sort of way.

On the contrary, then, I do not think you can stop the trouble by legislation. I think you can only stop it by courageous, constant efforts to get hold of these men by appealing to their best sentiment.

As to the question of the minimum of punishment. I do not want to be misunderstood about that. I should not place the maximum punishment any higher than it is to-day, because, as the men who have practised in the criminal courts will tell you, the minute you make the punishment too drastic, you defeat the very purpose of the statute. Leave the punishment where it is to-day, but strike out the provision limiting the courts to the minimum punishment.

On the question, finally, of the definition of the practice of medicine. While I want to be clearly understood as not expressing any opinion on certain questions, and while not agreeing or disagreeing with Dr. Fischer and his suggestion, I do think, as a matter of practical affairs, that the final definition will be best obtained by gradual steps, and that you cannot expect to accomplish in one legislature or in one year what may be to you the clearest and best definition of the practice of medicine. I have thrown out these suggestions to-night merely for the purpose of showing you how these questions are looked at by those of us who are officially in contact with them."

Leucemic Infiltration of the Accessory Sinuses.—An interesting condition of the mucous membrane of the accessory sinuses in leucemia is described by K. M Menzel (Zeitsch. f. klin. Med., Vol. 51, Nos. 3 and 4). Instead of a smooth lining, the sphenoidal sinus was clothed with a white membrane, presenting some 50 to 60 distinct protuberances between which there were extensive hemorrhages. All signs of inflammation were absent. This condition is of importance, as it may explain the uncontrollable epistaxis of leucemia.

A NEW METHOD FOR PERFORMING INTESTINAL ANASTOMOSIS.

BY JOHN W. KEEFE, M.D.,
OF PROVIDENCE, R. I.;
ATTENDING SURGEON TO THE RHODE ISLAND AND ST. JOSEPH'S HOSPITALS.

MUCH has been written upon the subject of intestinal anastomosis and at the present time there are eighty or more methods of uniting the ends of the resected intestine. It is a fact that more sutures have been devised for this than for any other branch of the entire field of surgery. Remarkable ingenuity has been shown by surgeons in the various methods employed, both in the insertion of the sutures and in the use of appliances to aid in the operation.

In the method I describe the Lembert interrupted and the Cushing right angle suture are to be made use of. In the majority of methods described these sutures seemed to be very favorably looked upon. I also use another suture a modification of the Lembert interrupted; which has all the advantages of the latter. It not only

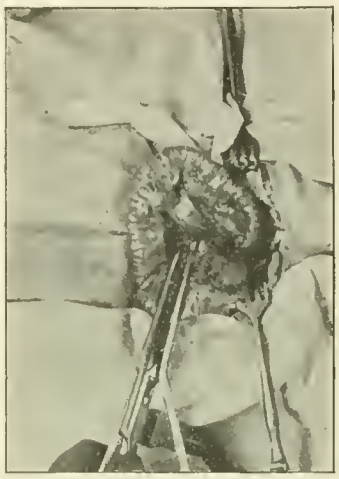
Fig. 1.

Intestine to be excised drawn through abdominal wound.

holds the peritoneal and muscular coats of the intestine in firm apposition at the mesenteric border but also serves to unite the mesentery at this point where leakage and infection very frequently occur. I learned from my experiments upon the dog that with the interrupted and modified Lembert sutures there is a very rapid union of the serous surfaces and with the sutures properly inserted these peritoneal surfaces are protected and firmly supported by the strong intestinal walls.

To sever the diseased tract of intestine and to separate the mesentery from it I use the Downes' electrothermic angiotribe. Among the many advantages this instrument possesses, not only in this operation, but in others, are, immediate hemostasis; perfect asepsis and cleanliness throughout the entire operation; an immunity from soiling with pus, blood and feces; the dispensing with the ligature; no secondary hemorrhage from slipping of ligatures or subsequent infection from the same, since there is not the puckering and con-

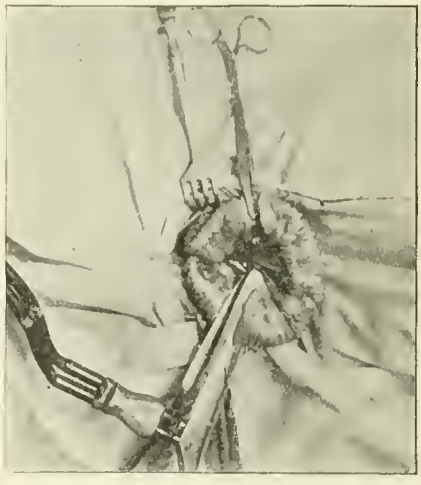
Fig. 2.



Electrothermic angiotribe and guard clamp applied to intestine at first point of section.

striction of the tissue which the ligature causes. With the angiotribe, in this particular operation we encounter no difficulty from a distended intestine, as is frequently the case when we use other appliances, nor do we need fear the foreign body in a gut with a small lumen. The angiotribe is an instrument readily applied, easily understood and a profound knowledge of electricity is not essen-

Fig. 3.



Small clamp applied to desiccated strip left after removal of electrothermic angiotribe and angiotribe applied to second point of section of the intestine.

tial in its manipulation. For these reasons it is invaluable in modern surgery and indispensable to the surgeon of to-day.

The technic of the operation is as follows:

After having drawn through the wound the tract of intestine to be excised, clamp the intestine at a right angle to its long axis with the three-eighth-inch blade of the electro thermic angiotribe and apply a current of 60 ampères for one minute. The compression of the clamp together with the heat generated by the electric current will produce complete hemostasis and occlusion of the gut with no extrusion of feces; therefore asepsis. Remove the angiotribe, and clamp the desiccated strip made by this instrument upon the intestine with a straight artery forcep as a precautionary measure to prevent leakage into the abdominal cavity, should the angiotribe have failed to completely close the lumen of the gut. In like manner repeat this process at the other point on the intestine where it is to be severed. After having done this sever the intestine by cutting through these two desiccated strips. Now the mesentery attached to this partially excised portion of the intestine is to be separated from it. Clamp this mesentery with the three-eighths-inch blade of the angiotribe and in as many sections as is necessary apply a current of 60 ampères for forty-five seconds each. The number of applications of the angiotribe on the mesentery depends of course upon the length of intestine to be excised. The desiccated strip made by the angiotribe on the mesentery will be found amply sufficient to prevent all bleeding, and further hemostasis with clamps or ligatures is needless. Separate the mesentery from the diseased structure by cutting through the path made by the angiotribe in the mesentery. Then remove the excised portion of intestine.

Fig. 4.

Electrothermic angiotribe applied to mesentery of portion of intestine requiring removal.

The desiccated ends are now to be approximated and their peritoneal surfaces united with a modified and an interrupted Lembert suture. The modified suture is inserted first and is passed through peritoneal, muscular and submucous coats of intestine one-eighth of an inch from desiccated strip near the mesenteric border of the intestine. Carry it out through the peritoneal coat on this side of the anastomosis and pass the needle through both layers of peritoneum where the peritoneum goes to form the mesentery.

Fig. 5.

Removal of portion to be excised, by cutting through desiccated strips with scissors.

Then carry the suture across and through both layers of the mesentery at a corresponding place on the other side of intended union. Now carry the needle back and through the mesentery again at the same point where we entered it the first time, then across again for the second time, through the same point where the mesentery was entered on this side of the anastomosis. In other words the stitch has been looped in the mesentery to strengthen this weak spot. This stitch is completed by passing the needle through peritoneal, muscular and submucous coats on this side of the union and out through the peritoneal coat of intestine.

The interrupted Lembert suture is then inserted at opposite poles on the intestine to the stitch previously made. This suture is passed on one side of the wound one-eighth of an inch from the desiccated strip through the peritoneal, muscular and submucous coats and out again through the peritoneal coat on the same side of the desiccated strip. It is then carried across the two desiccated strips and inserted on this side of the proposed union in the same manner as on the other side. The main point to be borne in mind when placing these two Lembert sutures and the Cushing suture also is not to penetrate the mucous coat of the intestine but to have it enter the submucous coat that we may rely on the tough, fibrous character of this layer. With these two stitches in place we have the ends of the intestine approximated. With the two ends of the intestine in apposition the desiccated strip of mesentery is left in the form of a loop. I unite these edges of mesentery with a Cushing suture, placing the stitches one-eighth of an inch from the

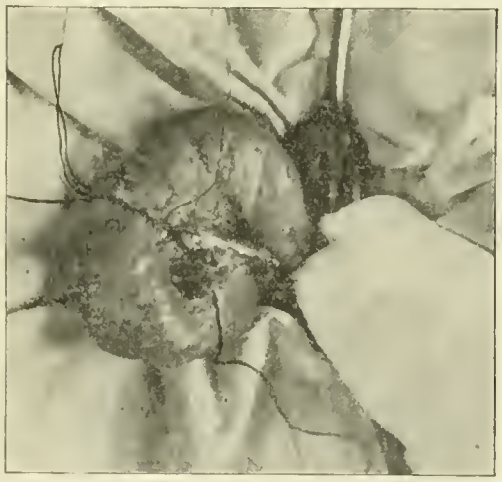
desiccated strip made by the application of the angiotribe.

To further unite the peritoneal surfaces and walls of the intestine I now use a Cushing right angle suture bearing in mind also not to penetrate the mucous coat. Begin the suture one-eighth of an inch from the desiccated strip on one side of the anastomosis and pass the needle through peritoneal, muscular and submucous coats of the intestine and out through serous coat on one side of union then carry it across the two desiccated strips to the other side at right angles to this stitch through the same coats of intestine as on the other side. On this same side of the desiccated strips make a stitch at right angles to this horizontal stitch, then carry the needle across the desiccated strips again at right angles to this short stitch, parallel to the horizontal one and through the intestine as before. Continue the suture in this manner until the entire circumference of the gut is encircled with it. The suture is then tied but before doing so the forceps used to clamp the intestine are removed.

Now invaginate the intestine with the finger and use sufficient force to make a lumen through the desiccated strip. Press gases and feces through the anastomosed ends to see that there is no leakage. Drop intestine back and close abdominal wound in the usual way.

The advantages of this method are immediate hemostasis; perfect asepsis, since there is no soiling with feces; no intestinal obstruction; no eversion of mucous membrane; little danger of cicatricial stenosis; a firm, strong union and a rapid operation.

Fig. 6.



Modified Lembert and right angle Cushing sutures in place.

I have performed eight operations upon dogs with a view of developing an aseptic method of making resections of the stomach and intestine, by the aid of the Downes electrothermic angiotribe. In one instance I removed the stomach and united the esophagus with the duodenum. The other seven operations consisted in resections of several inches of the ileum. We had in the case of gastrectomy some leakage of the stomach contents through the desiccated strips left upon removal of the angiotribe; owing I believe to the thickness of the stomach walls.

Fig. 7.

Anastomosis complete.

I am convinced that a larger electrothermic angiotribe with more crushing power would be of greater service in operations upon the stomach, than the instruments now in use. The angiotribe with the three-eighths-inch blade is well adapted for intestinal resections.

I performed my first operation November 2, 1902, and purposely allowed the ends of the intestine, remaining after resection with the angiotribe, to remain sealed by the desiccated strips alone; uniting the intestine by a lateral anastomosis with a Murphy button. This dog died in thirty-eight hours and the post-mortem examination showed a general peritonitis with extravasation of feces into the abdominal cavity, through the resected ends of the intestine, the desiccated ends having sloughed. There was good union and no leakage about the site of the lateral anastomosis with the Murphy button. This case proves the value of a purse string over the stump subsequent to the removal of the appendix with the electrothermic angiotribe.

An end-to-end anastomosis with silk Lembert sutures, following resection of the gut with the angiotribe, was made on the second dog. The desiccated strips sealing the resected ends of the intestine were allowed to remain closed after the insertion of a Cushing suture. The bowels moved thirty-six hours after the operation, showing that sloughing of the desiccated strips had taken place.

However, I believe that to complete the lumen of the intestine at the site of union, by invaginating the intestine with the finger and thus destroy the sealing by the desiccated strip, is desirable and should be done after the introduction of the Cushing suture.

One of the dogs had portions of the ileum resected on two occasions making a good recovery each time. He was intentionally killed four months after the first and one month subsequent to the last operation. The autopsy showed the mucous membrane to be perfectly smooth at the site of the operation wounds in the intestine, and no narrowing of its caliber. Another dog was intentionally killed fifty-four days after resection of a portion of the ileum. The autopsy revealed perfect union at the site of the operation. There were no adhesions and on opening the intestine and viewing the mucous membrane it was difficult to locate the line of union. Here again we found no narrowing of the caliber of the intestine.

I had an opportunity to carry out this method in man last March. The patient was suffering from intestinal obstruction and peritonitis due to a gangrenous, incarcerated, scrotal hernia. He had been ill some time and was in a poor general condition. I performed the operation with the aid of cocaine, removing 14 inches of the ileum with the aid of the Downes electrothermic angiotribe; uniting the ends with a modified Lembert and a Cushing suture.

The man made scarcely any complaint while the intestine was being resected. The cocaine was injected into the skin and ileohypogastric and ileo-inguinal nerves. The patient died four and one-half days following the operation from a continuance of the peritonitis present at the time of the operation.

A post-mortem examination showed a general peritonitis, with good union at the site of the intestinal anastomosis. No gas or intestinal contents could be pressed through the bond of union.

The excision of the portion of the intestine was performed very easily and rapidly with no extrusion of feces from the bowel.

Another Laboratory Plague Death.—The chief of the bacteriological laboratory of the Imperial Institute of Experimental Medicine died of the plague on January 20. He became ill on January 16, after experimenting with living plague cultures, and repeated injections of anti-plague serum were unavailing.

A FATAL CASE OF CHOREA COMPLICATED BY ENDOCARDITIS, PERICARDITIS AND NEPHRITIS.*

BY AUGUSTUS A. ESHNER, M.D.,

OF PHILADELPHIA;

PROFESSOR OF CLINICAL MEDICINE IN THE PHILADELPHIA POLYCLINIC; PHYSICIAN TO THE PHILADELPHIA HOSPITAL; ASSISTANT PHYSICIAN TO THE PHILADELPHIA ORTHOPEDIC HOSPITAL AND INFIRMARY FOR NERVOUS DISEASES; PHYSICIAN TO THE HOSPITAL FOR DISEASES OF THE LUNGS AT CHESTNUT HILL; ETC.

THE report of a single clinical case is justifiable only if it teach some important truth or establish some useful principle. This requirement is, I believe, fulfilled by the history to be related, inasmuch as it has distinct bearing upon the etiology, the pathology and the treatment of a not uncommon disorder.

There was brought to me on December 29, 1902, the ten-year old daughter of a neurotic father, who within twenty-four hours had been observed to exhibit twitching of the fingers of the right hand, then of the fingers of the left hand, and next of the right foot. There was also slight pain on movement on the palmar aspect of the right wrist-joint. For a month the child had been thought to have a "bad stomach," suffering from impairment of appetite and eating but little. She slept well and she had not been considered "nervous," though she had never been robust. She had had sore throat, perhaps diphtheria, three years previously and measles, whooping cough, chickenpox and mumps in early childhood. One maternal aunt and the paternal grandmother were said to be rheumatic, and another maternal aunt and two paternal cousins had had chorea.

On examination the heart was found overacting and a blowing systolic murmur was audible at the apex. The temperature was 100.3° F. Believing the case to be one of beginning chorea I directed five drops of Fowler's solution of potassium arsenite to be given three times a day, and in view of the possibility of a rheumatic relationship I also prescribed five grains each of sodium salicylate and sodium bromide likewise to be taken thrice daily. I was not able to decide whether the endocardial murmur was recent or old, although by reason of its softness and of the overaction of the heart, together with the elevation of temperature, I suspected the former. Accordingly I had the child put to bed. The temperature continued elevated, reaching as high as 102° F.; the pulse remained frequent, ranging about 120; the heart-murmur persisted; and slight twitching appeared in the muscles of the face. Pallor was marked. On January 12 the urine was noticed to be turbid and brownish, and examination disclosed the presence of albumin, together with leucocytes in moderate number. The specific gravity was 1.020, the reaction was acid, and there was no response to Fehling's alkaline-copper test for sugar. The mixture of salicylate and bromide had been superseded by

* Read before the Medical Society of the State of Pennsylvania at York, Sept. 23, 1903.

solution of potassium citrate and tincture of iron chloride twenty drops, each, thrice daily. On January 17 hyaline, granular and epithelial tube-casts in large number were discovered in the urine in addition to the albumin, and a loud to-and-fro friction murmur was audible over the body and at the base of the heart. A small cantharidal plaster was applied to the precordium and for the iron and the potassium citrate tincture of digitalis 7½ minims with 2 fluidrams of Basham's mixture of iron and ammonium acetate were substituted. Fearing that the arsenic might increase the existing disturbance in the kidneys the Fowler's solution was withdrawn.

The patient continued to do well and exhibited exceedingly little movement until January 18, when she was greatly frightened in consequence of the burning out of an electric circuit in the room in which she lay. Shortly after this accident she became restless and jerky, and speech, which previously had been unaffected, was greatly interfered with, and the peevishness, captiousness, obstinacy and restiveness present were increased. By January 21 the child was dull and soporose, yet irritable and cross. Sleep was poor and restless. About two pints of urine were being passed in the twenty-four hours, and albumin and tube-casts were still present. The heart continued rapid and the rough to-and-fro murmur over the body of this viscus persisted. The temperature fluctuated between 101° and 102° F. For several days the condition of the patient appeared greatly aggravated. She was exceedingly restless, crying a good deal and with much jerking and disturbed sleep. The administration of Fowler's solution was now resumed and sodium bromide was given in doses of five grains thrice daily. A change for the better set in. The patient began to sleep a little more and became more tractable; the rough heart-murmur grew less marked, although the area of cardiac percussion-dulness was increased and the apex-beat was outside the left nipple-line.

On January 27 the patient was again able to speak a little; she cried less; the heart-murmurs were less pronounced; the twitching was less marked; the urine was growing less turbid, the amount of albumin present and also the number of tube-casts less. In a short while only the soft systolic murmur heard at the first examination was audible at the apex. The pulse-frequency slowly but steadily declined. On February 1 the temperature had reached 99° F.; appetite was returning; the bowels were regular; sleep was sound and refreshing; twitching was less; the power of speech was increasing and speech was more distinct and less jerky. The urine still contained tube-casts, though in smaller number, and only a trace of albumin. From February 5 the presence of albumin in the urine could no longer be detected either by heat or nitric-acid contact; though casts persisted, but in progressively diminishing number. The patient now began to sit up, but she was pallid and weak, and speech, though greatly improved, was not quite perfect. Twitching had almost entirely ceased. Improvement continued steadily and the patient became somewhat stronger. On February 7 she walked a few steps, not without difficulty, and she spoke more and better. The action of the heart was rhythmic, though rapid, and the soft systolic murmur at the apex was still audible; the pulse counted 108 in the minute. Pallor and weakness remained marked features, the former assuming an extraordinary ashen character, and the latter becoming extreme. Puffiness of the face appeared on February 15 and shortly afterward the legs became swollen. The dose of Fowler's solution was diminished, while the digitalis and Basham's mixture were continued. Dyspnea now developed and became gradually more marked, and death resulted on February 18, apparently as a result of heart-failure, due, I suppose, to myocarditis. No autopsy was held.

Summary: We have here a case of chorea in a child of neurotic heredity, with slight rheumatoid symptoms and signs of endocarditis, in which striking relief was afforded by the administration of appropriate remedies, but in which a marked exacerbation of the choreic manifestations followed upon a severe fright, and in the sequence of which there developed pericarditis, nephritis and myocarditis, and, finally, a grave anemia, with a fatal termination.

The specially interesting features in this case are the association with chorea of rheumatoid symptoms, endocarditis, pericarditis and nephritis, the control of the spasmodic movements by arsenic and the intensification of the symptoms in the sequence of emotional disturbance (fright), and the fatal termination. The frequent coincidence or sequence of chorea and muscular and articular pain and swelling is a well-recognized fact, occurring in about one-fifth of the cases. By some chorea is looked upon merely as a manifestation of rheumatism. Endocarditis is a common complication of chorea, having been observed in 62 among 73 fatal cases collected by Osler,* who makes the statement that "*there is no known disease in which endocarditis is so constantly found, post mortem, as chorea;* it is exceptional to find the heart healthy." Pericarditis is less common, having been present in 19 of the cases, while nephritis is still less common, although Osler expresses the opinion that it is probably not so rare as has been thought. Inasmuch as chorea may be safely looked upon as an infectious disease, or at least as a manifestation of some infectious process, it is not difficult to understand that such complications as those mentioned should occur, perhaps as a varied result of a common cause. The same interpretation may be applicable to articular symptoms when these are present. How emotional disturbances act in the etiology of chorea, as in that of some other diseases, as for instance exophthalmic goiter, is beyond our present knowledge, although it may be surmised that it gives rise to

* Osler: "On Chorea and Choreiform Affections," P. Blakiston's Son & Co., 1894.

certain metabolic disturbances, probably through the intermediation of the nervous system. It is a popular notion that fright is a common exciting cause of chorea, but this is only in part sustained by the facts in the case. At any rate, while fright played no part in the determination of the attack in the present case the symptoms were greatly aggravated during a quiescent period in the sequence of fright, although this was coincident also with the development of symptoms of acute nephritis and the withdrawal of arsenic. The condition of the patient at this time was so grave, the apathy was so profound, the prostration so great, the movements so violent, that I feared the patient had become uremic and would be overwhelmed by the intoxication. On resuming administration of the arsenic, improvement at once set in and although somewhat slow, it was distinct and steady until the symptoms of heart-failure, which I attributed to myocarditis, and profound anemia appeared and led to a fatal issue. We have here additional evidence of the specific utility of this valuable drug in the treatment of chorea.

I have in a previous communication (Medical News, February 7, 1903) reported a fatal case of polyarthritis complicated by choreiform symptoms and vegetative endocarditis occurring in a young man, seventeen years old, observed in my service at the Philadelphia Hospital.

NOTES ON THE WIDAL REACTION: (1) THE QUESTION OF DILUTION; (2) THE INFLUENCE OF JAUNDICE.*

BY E. LIBMAN, M.D.,
OF NEW YORK;
ASSISTANT PATHOLOGIST, MT. SINAI HOSPITAL.

The method used in making the tests upon which this paper is based was described in full in the Mt. Sinai Hospital Reports, Vol. I, and in the Medical News, March 29, 1902. As a rule, dried blood was used for the tests, but in quite a number of cases the tests were also made with serum. In the larger number of the cases of jaundice to which I shall later refer, serum was used. For the general practitioner the use of the dried blood is undoubtedly much more practical than the use of serum. We have found that the dried blood, if properly sent to the laboratory, gives practically the same results as serum. The drops used are best made a trifle larger than the head of a pin. Should larger drops be used care must be taken that the specimen be dried before the blood coagulates. In a large number of experiments we found that the blood gave a better reaction after three or four hours than when used just after drawing—even after twenty-four hours the dried blood gives good results.

Until the spring of 1902 we were accustomed to make our reactions in the dilution of 1 to 20 only, but as it was claimed by many authorities that reactions ought to be made in the dilution of 1 to 50, we made it a rule at that time to make our reactions in the dilution of 1 to 20 and 1 to 50 (time-limit thirty minutes and one hour respectively).

Previous to the spring of 1902 and since that time, we have examined the blood in 1,500 cases of fever. Of these, 550 were cases of typhoid fever. In the 950 cases which were not typhoid fever, a Widal reaction was never reported positive even in a dilution of 1 to 20. This certainly points to the reliability of a reaction in a dilution of 1 to 20 when interpreted according to the method of considering only complete reactions as being positive.

We believe that it is advisable, if possible, to make such a standard in the judgment of reactions, that the report of a positive agglutination reaction to the physician should be equivalent to labeling his case as one of typhoid. The practising physician is not interested in a report saying his patient has or has not an agglutination reaction—he wants to know whether his patient has typhoid fever or not.

We will admit for the sake of argument that among the 550 cases of typhoid fever there may have been some cases of paracolon infection, and that the presence of the agglutination reaction in a dilution of 1 to 20 may simply have been a group-agglutination; but, if such a mistake does occur, it is not a serious one, for to the clinician a case of paratyphoid fever is to be considered and handled, at least for the present, as one of typhoid fever.

The question arises, why do we continue making reactions in a dilution of 1 to 50 if we have had such reliable results with a 1 to 20 dilution?

We have been surprised to find, in some instances, a positive result in a dilution of 1 to 50 when the reaction was negative or not clearly positive in a dilution of 1 to 20. There are, we believe, at least two explanations of what seems so anomalous a condition. In some instances at least, it is due to the fact that in a dilution of 1 to 20 the lytic action of the serum is so marked that one cannot obtain a clear picture. In some cases the explanation lies in the existence of bodies known as proagglutinoids. According to Shiga the proagglutinoids are bodies which are developed from agglutins through extraneous influences; they possess a greater affinity for the bacilli than the unchanged agglutins; they have lost the group (agglutinophore) which is the carrier of the peculiar agglutinating power, but have retained the other group (haptophore) upon which depends their attachment to the bacteria. Shiga[1] in a very interesting paper on this subject, after referring to the previous observations of Bail, Eisenberg and Falk, gives an account of his own experiments which prove the existence of such bodies. A short account of these experiments will, I think, be of interest here. By heat-

* Read before the Section on General Medicine, New York Academy of Medicine, November 17, 1903.

ing dysentery immune serum to 60° C. for an hour, or by shaking it with chloroform or exposing it to sunlight for a number of days, he obtained a serum which would agglutinate dysentery bacilli in high dilutions and not in low, whereas previously it had agglutinated in low dilutions as markedly, or even more markedly than in high dilutions. He applied the term "proagglutinoid zone" to those dilutions in which the reaction disappeared. He not only succeeded in producing a proagglutinoid zone with typhoid immune serum by heating it for four hours at 60° C., but he could, by the prolonged addition of chloroform to dysentery serum, almost completely change the agglutinins into proagglutinoids so that a reaction could not be obtained in any dilution. Further experiments proved that the proagglutinoids were attached to the bacteria and that the proagglutinoid zone could be made to disappear if enough bacteria were added to a mixture of non-agglutinated bacteria and a serum containing proagglutinoids.

Notwithstanding the fact that a 1 to 50 dilution will occasionally give better results than a 1 to 20, it is necessary to make the 1 to 20 dilution, because this is frequently positive before the 1 to 50 dilution becomes positive. Among 165 cases of typhoid fever we found a coincident positive reaction in 1 to 20 and in 1 to 50 in 127 cases. In 12 cases the reaction was positive in a dilution of 1 to 20 two days before it was positive in 1 to 50. In some instances even sixteen days elapsed before the reaction became positive at 1 to 50, and in 8 cases which were positive in a dilution of 1 to 20 there was no reaction in a dilution of 1 to 50 during the time of observation of the patients in the hospital.

From all these data it is evident that it is essential in performing the agglutination test to use dilutions of 1 to 20 *and* 1 to 50. It is even possible that the 1 to 100 or higher dilutions might be positive when the lower ones are negative. On this point we have thus far had no experience.*

The other point upon which I wish to dwell is the question of whether or not jaundice *per se* can cause a positive Widal reaction. On this subject quite some observations have been made, which we shall detail before we refer to our experiences.

Honl and Eisenberg,[2] and Heller[3] found that icteric serum was possessed of a certain amount of agglutinating power. Greenbaum[4] found a positive reaction in a dilution of 1 to 16 in cases of jaundice. The most extensive observations and experiments, however, were made by Koehler.[5] Koehler used for his experiments sugar-bouillon cultures of the typhoid bacillus; his time-limit was two hours and he considered clumps of four to be significant of the presence of agglutination. In 10 cases of disease of the liver, of which eight were icteric, he found an agglutination reaction present in six. The highest dilution in which he obtained the reaction was 1 to 40; very rarely 1 to 50, and once it was only 1 to 10. His first set of experiments was made with several varieties of bile. In the bile of dogs in which the common bile-duct had been ligated, he found a decided agglutinating power (even up to 1 to 160). Rabbit's bile was possessed of very slight agglutinating power. Human bile obtained at autopsy occasionally showed a distinct agglutinating power (up to 1 to 80). He had no opportunity of testing bile obtained intra vitam. In the bile of typhoid patients post mortem he found no increase in agglutinating power over the bile in other diseases.

In attempting to ascertain what constituent of the bile was responsible for the presence of the agglutinating power, he tested taurochol, glycochol, bilirubin, biliverdin, cholalic acid, glycocholic acid, cholesterin and sodium taurocholate, but found that none of these was possessed of any agglutinating power. Solutions of taurocholic acid, however, gave some positive results (up to 1 to 60). He obtained no result with the serum of rabbits into which he had injected taurocholic acid, but did obtain some positive results in dogs. The reaction generally appeared two or three days after the injection and lasted several days. He obtained results even with some samples of taurocholic acid which in themselves were possessed of no agglutinating power. The serum of dogs in which the bile-ducts had been tied off gave a slight agglutination reaction which disappeared after a communication was established between the gall-bladder and the intestine. On later injecting taurocholic acid into such animals, an agglutination reaction could again be obtained varying in strength from 1 to 40 to 1 to 50. The results in these experiments were not constant.

These experiments of Koehler's are of great interest in showing that taurocholic acid and bile cause a certain amount of agglutination, but they are not significant practically because in making diagnoses by means of the Widal test we deal only with complete reactions. This remark also holds true of his observations on the presence of an agglutinating power in the serum of patients with jaundice. For practical purposes it is inadvisable to use sugar-bouillon cultures, a time-limit of two hours is too long and we shall see that later observations on the whole are contradictory.

Sailer[6] in three cases of intense jaundice obtained no reactions. Zupnik[7] in seven cases of jaundice (two cases of cholelithiasis, one case of cholecystitis and four cases of Weil's disease) found "a more or less positive reaction." In two other cases of Weil's disease the reaction was negative. In one case of carcinoma of the

* Since writing the above we have encountered one case of typhoid fever in which the reaction was absolutely complete in a dilution (approximate) of 1 to 400 in one hour, and negative at all dilutions below and above. After four hours, there was slight clumping at 1 to 200, and stoppage of motility at 1 to 800; 1 to 1,600 was absolutely negative. This case was a typical one in the practice of Dr. Albert Kohn. It would seem necessary, therefore, in cases suspected of being typhoid fever, to make the test in a large number of dilutions.

liver without fever he found a positive reaction. He used both macroscopic and microscopic reactions in a dilution of 1 to 40 with a time-limit of eight hours. It is unfortunate that he does not state what he considers to be a positive reaction, and the time-limit is too long.

Eckhardt[8] describes two cases with a clinical picture of Weil's disease of one month's duration in which the reaction was positive at times in a dilution of 1 to 1,000. In these cases the agglutination reaction persisted even after the jaundice had disappeared. In eight cases of jaundice he obtained a positive reaction in a dilution of 1 to 100 in two hours and in one case up to 1 to 1,000. The bile obtained at autopsy and the bile obtained from biliary fistulæ was devoid of agglutinating power. He cites one case of jaundice in which the bile gave no reaction but the blood gave a positive reaction in a dilution of 1 to 100. There was no history of any previous typhoid infection. We will cite a case later which demonstrates that such a condition of affairs can exist in typhoid fever. He also unfortunately does not state what he considers to be a positive reaction. He is of the belief that his cases were probably cases of typhoid fever and bases his belief mainly on the persistence of the reaction after the disappearance of the jaundice. No further bacteriological examinations were made in the cases. We are also inclined to consider that his cases were typhoid fever, but in view of the fact that he obtained positive reactions so often in other cases of jaundice, we believe that less stress should be laid upon the significance of the reactions. In any event, the cases do not prove that jaundice *per se* can cause a positive Widal reaction.

Langstein and Meerwein[9] also made observations in a number of cases of jaundice. Their first case was one of obstruction of the common bile-duct by gall-stones with adhesions about the gall-bladder. The bile was possessed of no agglutinating power. The blood gave a positive reaction in a dilution of 1 to 100 in twelve hours. Later when some bile appeared in the stools they succeeded in obtaining only a partial reaction in a dilution of 1 to 20 in two hours. In two other cases of febrile jaundice in which the stools were not entirely acholic, the serum did not agglutinate the typhoid bacillus even in a dilution of 1 to 10; and in a fourth case of metastatic carcinoma of the liver there was an entire absence of any agglutination reaction.

Their first case is, however, not conclusive for two reasons. In the first place a time-limit of twelve hours is too long for a reaction in a dilution of 1 to 100, and secondly the question of whether the cholelithiasis could not have been due to typhoid infection is entirely ignored. The conclusion which has been drawn from these two cases that the serum of an icteric patient with cholangitis gives a positive reaction, whereas that from an icteric patient without cholangitis does not, is hardly warranted.

Joachim[10] describes two cases. The first was a case of febrile jaundice in which at the post-mortem examination purulent cholangitis and a thrombosis of the portal vein were found. In this case the blood gave a positive reaction with the typhoid bacillus in a dilution of 1 to 40 in two hours and 1 to 80 in fifteen hours (macroscopic and microscopic tests). From the spleen a paracolon bacillus was cultivated, which was agglutinated by the serum in a dilution of 1 to 40 in two hours. In the second case the jaundice was due to a carcinoma at the papilla of Vater, obstructing the common duct. The blood obtained from the cadaver sixteen hours after death(!) agglutinated the typhoid bacillus in a dilution of 1 to 10 in fifteen hours.

These observations also are of no great significance. In the first place the time-limit was too long for the strength of the reactions. The author does not state what he considers to be a positive reaction; and again, the reaction may have been a group-agglutination reaction. He believed that he was able to confirm the observation of Langstein and Meerwein that it is particularly in cases of cholangitis with jaundice that the blood gives a positive Widal reaction.

The observations of Koenigstein[11] are, we believe, more conclusive than any of those already mentioned. His reactions were made in a dilution of 1 to 10, 1 to 50 and 1 to 100 and were observed for a period of twenty-four hours. With bile he obtained only false reactions due to mucus, crystals and cellular elements. He could eliminate such reactions by filtering the bile. He examined 21 specimens of bile obtained at autopsy with negative results. The bile of rabbits and oxen also gave negative results. In two dogs in which he had produced jaundice by the subcutaneous injection of a hemolytic poison, he obtained a reaction in only 1 to 10 in one, and no reaction in the other. Among 11 cases of jaundice, seven gave no reaction whatsoever; the other four gave good reactions in a dilution of 1 to 10 and slight reactions in 1 to 50. He believes that in some cases such reactions may be group-agglutinations. He repeated Kochler's experiment with taurocholic acid, but could not substantiate his findings. When one knows that the writer considers an agglutination reaction to consist of agglutination with "incomplete paralysis of the bacteria" his negative results are doubly convincing.

Our own observations consist of tests made with bile and with the serum of jaundiced patients. Ten samples of bile were examined. These specimens were either normal bile or bile from cases of typhoid fever, chronic pancreatitis or cholelithiasis. In no instance could we get a positive Widal reaction. With some there was slight clumping, but in others there was absolutely no effect on the bacilli even in a dilution of 1 to 1. The sera of 35 cases of jaundice (exclusive of four cases to be described later) were tested. These cases included cases of appendicitis, malignant endocarditis, gall-stones with and with-

out cholecystitis, tumors of the liver and duodenum, diseases of the pancreas, a case of Weil's disease, two cases of acute yellow atrophy, a case of general miliary tuberculosis, some cases of catarrhal icterus, hypertrophic cirrhosis, one case of liver abscess with jaundice and cases of jaundice due to septic conditions. In not one of these cases was the serum possessed of any more effect on the bacteria than we often find in normal sera. Not one of them gave a reaction which was at all doubtful.

In only four cases in our experience have we met with a positive Widal reaction in patients with jaundice. The first case was one of paracolon infection reported by the writer in the *Journal of Medical Research* for 1902. In that case the patient had a positive reaction with the paracolon bacillus obtained from the blood in a dilution of 1 to 100 and the typhoid bacillus in a dilution of 1 to 200. At the autopsy healing ulcers were found in the intestine and the question had to remain an open one whether or not the patient suffered from a mixed infection due to the typhoid bacillus and the paracolon bacillus.

The second case was that of a woman who was in the hospital last year with an attack of typhoid fever complicated by cholecystitis. The Widal reaction was positive in a dilution of 1 to 50. She returned to the hospital yesterday with a severe attack of cholecystitis accompanied by marked jaundice and was operated upon by Dr. Lilienthal. The blood gives a positive Widal reaction in the dilution of 1 to 20. The bile and the markedly icteric urine give no reaction.

The third case was also one of typhoid fever with jaundice due to acute cholecystitis. The Widal reaction was positive in a dilution of 1 to 50 and typhoid bacilli were demonstrated in the fluid in the gall-bladder by Dr. Bernstein of the laboratory staff. The fluid in the gall-bladder in this case was not bile-stained, but consisted of thin seropurulent fluid. This fluid gave a positive Widal reaction in a dilution of 1 to 50.

The fourth case is one of such marked interest that I shall give the history in detail. The patient was a woman sixty-four years of age who was in good health up to the age of thirty-four years when she suffered from an attack of jaundice with severe colicky pains and passed gall-stones. There is no history of typhoid fever. One year before admission to the hospital she suffered from severe colicky pains, chills and vomiting; her skin became extremely yellow, the feces very light-colored, the urine very dark and she passed several gall-stones. She was well after this attack up to two weeks before admission to the hospital. Then she had a chill, vomited dark green fluid, had severe pain in the upper right quadrant of the abdomen and marked jaundice. She was operated upon by Dr. Lilienthal who found a large purulent exudate around the gall-bladder. The Widal reaction was positive in a dilution of 1 to 50 and typhoid bacilli were isolated by Dr. Bernstein from the pus found at the operation.

It will thus be seen that from our observations there is nothing which convinces us that jaundice *per se* can cause a positive Widal reaction, and have pointed out such deficiencies in the cases cited in the literature, that all we can state is that, while icteric serum may at times be possessed of a certain amount of agglutinating power, there is no definite proof at present that it can produce sufficient agglutination to interfere with our clinical diagnosis.

A BRIEF NOTE ON THE X-RAY TREATMENT OF GLANDULAR TUBERCULOSIS.*

BY FRANK P. VALE, M.D.,
OF WASHINGTON, D. C.

IT is now just a year since I had the possible value of the X-rays in the treatment of glandular tuberculosis, accidentally demonstrated to me, through the results obtained in the case to be reported this evening. For a year this patient has remained entirely well, until just within a few weeks, when he began to show evidences of a tuberculous intracranial lesion. His progress has been so satisfactory since again instituting X-ray treatment, and promises so well to continue to complete recovery, that I present him to you this evening for your examination, with the hope that I may be able to bring him before you in a few months, cured.

A year ago I knew of not one case of glandular tuberculosis thus treated, and have since naturally been on the lookout for reports of any such. Last winter I met the first reference to the subject in the third edition of Dawson Turner's manual, which had then just appeared. He briefly mentioned six cases of glandular tuberculosis, two of them cured and the others greatly improved, by exposures to the X-rays.

In the most satisfactory book on X-ray therapy which has yet appeared, that of Pusey and Caldwell, just from the hands of the publishers, I find reported five cases, in all of which there was more or less marked reduction in the size of the glands, and in one complete disappearance, from similar treatment. Pusey says as yet there is no literature on the subject, but that there is reason to believe a general attempt is being made at the treatment of this condition with the X-rays.

I have talked to a few physicians who devote their time to this class of work, without gaining much additional information. Dr. Ells-

* Read before the Medical Society of the District of Columbia Oct. 14, 1903.

worth, Dr. Williams' assistant at the City Hospital, Boston, however, was under the impression, without referring to their records, that several such cases had been successfully treated in the clinic, and thought they were reported in Williams' book. But on consulting it I find only the general statement, that even the largest tubercular glands respond surprisingly well to treatment with the X-rays.

The case I present this evening is also most interesting as an illustration of the difficulty, at times, of differentiating the early stages of primary glandular tuberculosis and Hodgkin's disease. The identity of the two diseases has been much discussed, but I think at last disposed of negatively by recent work, notably that of Reed, as recorded in the Johns Hopkins Hospital reports for 1901-2 (p. 131). To understand the extreme loss of weight of this patient it is necessary to bear in mind the more severe manifestations of glandular tuberculosis as seen in cases, for example like that of Delafield (*New York Medical Record*, 1887, p. 424). Such cases bear the same relation to the chronic forms of glandular tuberculosis, that "galloping consumption" does to fibroid phthisis. Courmont, Tixier and Bonnet (*Jour. de Physiol. et de Path. Gen.*, 1889, 1, p. 826) report a case similar in almost every detail to mine. Another similar case is that reported by Ardouin (*Bull. de la Soc. Anatomique de Paris*, November, 1897, p. 846). These cases of "Lynphadénie Aleucémique" due to the tubercle bacillus have also been studied by Dulcion (*Bordeaux Thèses*, 1896), Sternberg (*Zeitschr. f. Heilk.*, 1898, Bd. xix, p. 21), and others.

I hesitated to employ tuberculine for diagnostic purposes, because the profession is not yet of one mind as to the harmlessness of this procedure, though I think the testimony of Osler, Whitaker, Anders, Trudeau, Shattuck and others should lead us to its adoption. In five cases of Hodgkin's disease in the *Johns Hopkins Hospital Bulletin* just referred to, tuberculine gave negative results, and Reed also states that bad effects from its use have not been seen.

Mr. S. came to me the middle of July, 1902. He had never been sick until present illness began, six months ago, when he noticed a slight swelling on the left side of his neck. Its increase in size has been very slow, but he has progressively lost weight, amounting now to 55 pounds. He has never had syphilis or any other venereal disease. His family history is uninteresting save for the not very significant fact that of nine children, two sisters died of tuberculosis.

A careful examination threw no further light on his trouble. A blood examination showed a slight secondary anemia, with leucocytes about normal as to number and kind. My first impression, as I told him, was that the swelling was tuberculous.

September 1 of the same year he again reported to me. He had lost an additional ten pounds in weight. During my absence from the city in August he consulted one of our leading surgeons, who advised against any operation, without committing himself to a diagnosis. Largely influenced by this opinion, and thinking he leaned toward a diagnosis of Hodgkin's disease, I began exposing the affected side of the neck twice a week to the X-rays, for fifteen to twenty minutes. He had taken no medicine, nor did I then prescribe any.

Imagine my delight at seeing the man rapidly improve. In two weeks he had made the astonishing gain in weight of fifteen pounds. During another four weeks he almost entirely regained his normal feeling of well being and strength, though the further gain in weight was only a few pounds. The swelling in the neck had been reduced one half in size. It was very apparent to myself, and all his friends, he was rapidly getting well. I desired much to know what I was curing, and requested permission to cut out a piece of the swelling for microscopical examination, to which he consented with the suggestion that if the mass could be removed without danger it should be done.

I found three enlarged lymphatic glands, about the size of walnuts, lying deeply under the sternomastoid muscle. Above and below the other glands of this deep lymphatic chain were also enlarged, but not to the same extent, nor sufficiently to have allowed them to be palpated, on account of their deep situation. The incision was extended from the clavicle to the mastoid process and all the glands removed with the exception of two, high up under the angle of the jaw. These were left, as their relations were such that their removal would have added greatly to the risk of the operation.

Under the microscope there was the unmistakable histological picture of tuberculosis—the entire section showing caseous degeneration, with the structure of individual tubercles faintly discernible in places.

Nothing further was done for the patient. After a temporary loss of five pounds following the operation, he rapidly gained in weight. The two glands left under the angle of the jaw increased in size for the first four months, until they could be seen as well as felt. Then they gradually grew smaller and at the end of ten months had entirely disappeared, and the patient had gained in all forty-five pounds, or within about twenty pounds of his normal weight of two hundred and twenty.

He remained in good health until this fall, when he reported to me again about the first of September. He has lost eight or ten pounds in weight. He complains of loss of sense of taste; of his tongue feeling swollen; and of his left arm and leg being numb and weak. His speech is hesitating and thick, and cerebration is not normally active. His memory is poor. His tongue projects to the right side. The knee-jerk on the left side is markedly exaggerated. He cannot support himself on the left leg alone. These symptoms very clearly pointed to an intracranial

lesion, which, in view of his previous history is undoubtedly tuberculous—involving the meningeal lymphatics. The gradual appearance of these symptoms and the prompt improvement which again followed exposures to the X-rays, without any other treatment, supports this interpretation. There is a high blood pressure of 210 mm., but this, in my opinion, is not to be taken as an evidence of arterial disease, but simply a result of the localized meningeal tuberculosis. The radial arteries are soft, heart normal in size, urine normal in quantity and containing no trace of albumin, and in fact nothing to suggest an arteriosclerosis. A syphilitic endarteritis would not have thus responded to X-ray treatment. Several physicians who have seen this patient with me have suggested the administration of potassium iodide. He has not taken a drop of medicine, however, since he came under my care.

In endeavoring to satisfy myself that the involvement of the cervical lymphatics was the sole cause of all his loss in weight I took several radiographs of the chest, which I think would have revealed any associated trouble in the lungs.

His improvement already, at the end of a month of renewed X-ray treatment—exposing the head to the rays three times a week—has been most satisfactory. He can support himself on his left leg—showing its increased strength—and feels generally much better. Even though the ultimate result is not what I now expect, the beneficial effects of the X-ray treatments have been so marked I deem it of sufficient interest to bring the matter before you.

[NOTE.—December 17, 1903. Two months have elapsed since the above communication was read. The patient is now practically well and has returned to his work. For a short time he did not show any further improvement. Dr. Belt examined his eyes for me again and reported that the papillæ were redder than normal and that in each eye there was a small patch of choroiditis. I increased the frequency of the X-ray treatments at two feet with a high vacuum tube excited by a powerful coil, and soon he again showed further progress toward cure. Dr. Belt reports to-day that all evidence of the choridial trouble has disappeared. The patient is quite himself mentally. I find the exaggerated knee-jerk on left side has disappeared also, and that the power in left arm and leg is about normal. He says the feeling of numbness and cold in them is gone.]

Encouraged by this result I have used the X-rays in one other case, one recently discharged from the Sanitarium at Saranac Lake as "arrested." The lungs in this case were affected secondarily to the tuberculous process in the cervical glands. The lungs had rapidly improved at the Sanitarium, but the glands had increased in size. The advisability of their removal was considered by his physicians there, but decided against for fear of bringing the tuberculous process in the lungs into renewed activity. On his way to the Southwest he stopped in Washington for two weeks, and I exposed the glands daily to the X-rays. Even during this short time they diminished appreciably in size, and a few weeks later he wrote me they were hardly half as large as before.

MEDICAL PROGRESS.

MEDICINE.

Behavior of Proteids in Diabetes.—In severe forms of diabetes part of the proteid molecule itself is excreted as sugar, but it is interesting to note that the various kinds of proteid behave differently in this respect. Thus the ingestion of casein may increase the glycosuria considerably, while globulin from the blood and ovalbumin may have little influence. It may be stated that albumin, which is rapidly decomposed in the body, is apt to aggravate the diabetes. In a patient observed by W. FALTA (Corresp. f. Schw. Aerzte, Nov. 15, 1903) the glycosuria rapidly disappeared when meat was substituted for yolk of egg, which, by virtue of its lecithin, also exerts an unfavorable influence upon the assimilation of sugar.

Etiology of Aneurisms of the Aorta.—Aortic aneurisms caused by trauma in perfectly healthy individuals are very rare, but certainly do occur. H. ARNSPERGER (Deutsch. Arch. f. klin. Med., Vol. 78, Nos. 5 and 6) believes that small tears are replaced by cicatricial tissue which cannot withstand the continuous pressure. The injury is generally very severe and directed against the thorax. Infectious diseases as a cause are of more importance in the smaller vessels than in the aorta, but it is possible for an infectious thrombus to lead to ulceration with weakening of the walls or for an acute aortitis to be followed by predisposing, chronic changes. Alcohol, nicotin, lead and senile atheroma all play a subsidiary rôle as compared with syphilis. The pathological study of most all aneurisms will show lesions characteristic for lues and rupture of the elastic membrane, such as have been described by others, are hardly ever seen.

Infection with Eustrongylus Gigas.—A very peculiar case of chyluria has been very carefully studied by D. STÜRTZ (Deutsch. Arch. f. klin. Med., Vol. 78, Nos. 5 and 6). The patient, an Australian, came to Europe to be cured of his disease, which had hitherto puzzled the physician, who had vainly sought for filaria in the blood. After many negative results, the author finally discovered in the urine an egg of *Eustrongylus*, a rare parasite found in animals and occasionally at autopsies. Since all treatment was unavailing, and the seat of the parasite could with probability be located in one renal pelvis, a nephrotomy was performed without discovering any lesion, so that a communication between ureter and lymphatic system was most likely seated lower down. A laparotomy was refused and the patient left without being cured of his chyluria. The case constitutes the first infection of its kind diagnosed during life. The parasite is one of the largest worms known and possesses a blood-red color; it prefers the renal pelvis of animals, and gradually brings about a pressure atrophy of the kidney and otherwise seriously endangers life. With filaria there is an actual obstruction of the lymph-channels with secondary rupture, but the *Eustrongylus* probably injures the vessels directly, and thus leads to very persistent fistulæ. It is likely that a long ether-narcosis will kill the animal, since no more eggs were found after the operation. An exact localization requires cystoscopy and ureteral catheterization. The worm is probably introduced into the system by eating uncooked fish. The eggs readily

develop in water or moist earth and an embryo escapes in five to six months, whose life-history is very short. The friability of the eggs probably explains the rare occurrence of the parasite. All attempts to infect fish and dogs with the voided eggs of the patient were unsuccessful.

Thrombosis of Renal Vein.—A very rare complication of chlorosis, thrombosis of the renal vein, has been observed by H. Reese (Deutsch. Arch. f. klin. Med., Vol. 78, Nos. 5 and 6). The patient had already recovered from a bilateral thrombosis of the saphenous veins when she was suddenly seized with vomiting, severe pain in the kidney region, pronounced albuminuria without casts and marked enlargement of the kidney. There also was a slight rise of temperature and a diminution in the amount of urine with rise of the specific gravity. The patient slowly convalesced with rest and iron, but three months later traces of albumin were still present in the urine. The most dangerous complication, pulmonary embolism, did not develop. The case illustrates well that iron is not a prophylactic for thrombosis, for the patient had been taking Blaud's pills for weeks before the complication appeared.

Etiology and Pathogenesis of Black-water Fever.—There are three facts which seem to point against the identity of black-water fever with malaria: The distribution of both diseases is not the same, parasites are not generally detected in the blood in the former disease and quinine is without effect. These statements, though correct, are apt to mislead, according to A. Plehn (Virchow's Archiv, Vol. 174, No. 3). The fever occurs in malarial regions near the tropics; the reason it is not more common in cooler climates is because the system has time to recuperate from the infection during winter. Plasmodia are not found because the disease really constitutes an acute disintegration of red cells, thus setting free the plasmodia, which rapidly dissolve in the serum; if the blood is taken very early in the attack, they can generally be detected. The inefficiency of quinine is also evident from this; since it also induces hematocytolysis, it is clear that it is more apt to do harm. Two factors are necessary to induce an attack: a predisposition and some inciting cause. The predisposition is caused by an intense, continuous and often insufficiently treated infection, such as is common in the tropics. Any variety of parasite may be found, but the estevo-autumnal form is most common. No doubt the number and virulence of the unknown latent form which keeps up the infection during the afebrile period, plays an important part. A diminished resistance of the red cells, probably a manifestation of functional exhaustion on part of the overtaxed blood-forming organism is invariably present, together with an unstable condition of the entire nervous system. The exciting cause of the attack is usually a dose of quinine or some other drug tending to injure the cells; less frequently, a cold, some injury or an emotion is mentioned. The attack is initiated by a severe chill, cardialgia, cyanosis and dyspnea; soon the skin becomes jaundiced and the patients complain of burning on urination. The jaundice is peculiar in that it lacks the greenish tinge and is usually not accompanied by itching. Despite the presence of bile in the blood, and often in large amounts in the feces, the urine generally does not contain appreciable quantities. If the blood is examined during the height of the attack, few changes are noticed besides an anemic condition of the cells, since all abnormal and less resistant forms have already disintegrated. Thus with 20 per cent. hemoglobin and one million red cells, the latter may appear almost normal. In two to three days the jaundice and albumin disappear and the hemoglobin begins to rise, generally by 2 to 3 per cent. daily. There is every reason to believe that the chief destruction of red cells goes on in the liver and spleen. The renal changes are not due to an actual nephritis, but to a functional disturbance of renal activity; when anuria develops, it has a purely mechanical cause and is usually not followed by uremia.

Excretion of Salts in Nephritis.—If a healthy person is kept on a uniform diet for several weeks and then a certain amount of chlorides, phosphates and sulphates be given, these salts may be excreted in twenty-four to forty-eight hours, but occasionally the excretion may begin only in twenty-four to forty-eight hours and last for three days or more, even where there is no nephritis. E. v. Koziczkowsky (Zeitsch. f. klin. Med., Vol. 51, Nos. 3 and 4) has studied the same question in nephritis and finds that in cases without edema, two types may be recognized as far as the chlorides are concerned. In one, the ingestion of a medium quantity of salt is followed by diuresis with a diminished percentage, in the other the percentage is constant and not influenced by the amount of urine. In incompensated nephritis with edema, the percentage is frequently diminished, if salt is given. There seems to be a distinct antagonism between chlorides and phosphates, for the latter are excreted most freely where the retention of chlorides in the system is greatest and vice versa. The same holds true for the sulphates. From a prognostic point of view, an increased excretion of chlorides in nephritis, after a period of retention, is a favorable sign, hence a diminished excretion, an unfavorable one. A prolonged increased discharge of phosphates will speak for a retention of chlorides. A drug, such as diuretin, which would wash the chlorides out of the system, would have a favorable influence upon the edema were it not for the injurious effect upon the renal epithelium. Heart tonics are in place, as they help unloading the system of salt, but salt itself should be restricted in the diet. The so-called thirst-cures do not rest upon a sound basis, since the retention of salt and not that of water is the primary cause of edema. If saline intravenous or subcutaneous infusions should be necessary in the course of the disease, they should be hypotonic, that is, should contain less than 0.91 per cent. of salt.

Antistreptococcus Serum in Articular Rheumatism.—The employment of sera in this disease has been made the subject of careful study by Menzer, who claims that the lymphatic ring in the pharynx affords the point of entrance for the cocci. His serum is produced from streptococci derived from the anginæ associated with articular rheumatism. As the serum is not passed through animals, however, exact dosage is not possible. A. Schmidt (Berl. klin. Woch., Dec. 7, 1903) has lately made a test of this agent in 15 cases, most of which were characterized by an early passage from the acute into the chronic stage, and in which other remedies had met with little or no success. From one to eight injections were given in each case, the dose varying from 5 to 20 c.cm. The quantity was rapidly increased until a distinct reaction was obtained, the next injection being then delayed until the effects of the other had fully subsided. The reaction varied greatly in different patients. In some there was high fever and marked local changes, in others only the latter appeared and in a few no change at all took place. Local reactions were only observed in the joint where the injection had been made, the others remained free. In summarizing his results the author states that definite benefits were seen in six cases, a certain degree of improvement in four and no effects at all in five. The good effects consisted in an abatement of the pain and increased mobil-

ity. The author does not believe that this serum exerts a specific action similar to that produced by diphtheria serum or tuberculin. He admits, however, that undoubted results have been obtained especially in the subacute cases. In acute cases very little effect was observed and in chronic cases none at all. It does not seem advisable to employ the serum until all other methods have failed and a better standardizing is at present a great desideratum.

Etiology of Yellow Fever.—A report has been published recently containing the results of investigations by the U. S. Marine Hospital Service, in which is described a protozoan parasite found regularly in certain mosquitoes that had bitten yellow fever patients. To this organism was given the name of *Myxococcidium stegomyiæ*. JAMES CARROLL (Jour. Am. Med. Ass'n, Nov. 28, 1903) has carefully investigated these claims and believes that the question does not stand the test of scientific criticism. He shows that the fusiform stage of this organism is not connected in any way with the transmission of yellow fever. It is apparently not a protozoan parasite, but a yeast fungus in its fusiform stage, the only form in which it is constantly present, it shows the characteristic budding, staining affinities and spore formation of a blastomycete, and it is found with considerable regularity in both male and female mosquitoes that have been purposely fed on overripe bananas to which a culture of wild yeast has been added in the laboratory. The organism has not hitherto been found in repeated examinations of mosquitoes of the genus *Stegomyia* that have bitten yellow fever patients in the early stages of the disease, when such insects had been fed only on blood, dry sugar and water. This statement applies only to mosquitoes that are known to have reproduced the disease in human beings.

Titration of Gastric Juice.—This curious observation has been made by F. VOLHARD (Münch. med. Woch., Dec. 15, 1903), who states that if some albumin is added to gastric juice, phenolphthalein will eventually give much higher values than at first, and the change of color will take place considerably later than with litmus. This is best explained by the fact that peptone binds alkali just as readily as it does acid and that phenolphthalein indicates only the presence of free alkali. It is therefore much more accurate to determine the total acidity with alizarine or with red and blue litmus paper. Töpfer's method is based on wrong principles, but gives fairly accurate results; the alizarine does not indicate the free hydrochloric acid, but the total acidity and by subtracting the phenolphthalein figures from those obtained with alizarine, the combined alkali would be obtained which is about the same as the combined acid.

Detection of Blood in Gastric Contents and Feces.—The simple inspection of feces and gastric juice for the presence of blood is never sufficient since small amounts will not alter the color. The spectroscopic method is very convenient, though it demands an expensive apparatus; where this is at hand it is best to convert the hemoglobin into hematoporphyrin by the addition of a small amount of concentrated sulphuric acid. D. SCHMILINSKY (Münch. med. Woch., Dec. 8, 1903) prefers the guaiac test to the hemin test, since the amount of material employed in the latter is too small. Great attention must be paid to the diet and everything containing blood or chlorophyl should be carefully avoided. Where there is no danger of a large hemorrhage, some slightly irritating food, such as coarse bread, may be added so as to slightly irritate the ulcerated surface. The examination begins on the third day and all hemorrhage from the nose, mouth or anus must be carefully ruled out. Frequently it is impossible to avoid slight bleedings with the stomach-tube; in such cases the feces alone must decide. A small amount of these are mixed with acetic acid and then shaken with ether, which is poured off after the fluids have separated and then mixed with five drops of a 1 to 5-per-cent alcohol solution of guaiac, and ten drops of oil of turpentine or peroxide of hydrogen. In the presence of much blood the ether will turn bluish violet or blue; with smaller amounts there is a definite play of colors in the case of feces: First green, then brownish-red, then violet, and finally blue. With small amounts of blood, green alone may result; this is not, however, characteristic for blood. Where the test is repeatedly positive, the presence of an ulcer, cancer or a severe disturbance of motility is almost certain.

Cyclical Albuminuria.—A contribution to the etiology, prognosis and treatment of this condition, based on his clinical experiences, is made by HAUSER (Berl. klin. Woch., Dec. 14, 1903). He claims that it is necessary to distinguish more closely than heretofore between cases of orthotic albuminuria in which there are to be found occasionally a few structural elements in the sediment and those in which they are absent, even after repeated examinations. The former class he considers true nephritis. Most observers agree that the disease is very apt to follow acute infectious diseases or sometimes an acute nephritis. The author's material comprised 14 cases in which he made careful and repeated urine examinations for several years. These were grouped in two classes. In one the orthotic albuminuria developed after a mild or severe acute nephritis, which, in spite of appropriate treatment, never was fully cured. Here the formed elements gradually disappeared, but the periodical albuminuria remained. But even in the other set of cases, a previous infectious disease, most frequently scarlet fever, seemed to act as a causative factor. Another circumstance which showed an apparent connection between the two conditions, was the fact that the children who had presented a cyclical albuminuria at some time, readily developed an albuminuria sometimes with casts after comparatively slight infections, such as an angina. The author has found, moreover, that most of these patients present symptoms which clinically bear a close resemblance to nephritis. He believes that this form of albuminuria is probably due to circulatory disturbances, to the action of toxins or to the irritation produced by metabolic products which result from unusual muscular exertions. These act on a kindey impaired in its functionating powers by anatomical changes brought on by infectious processes, and result in an occasional excretion of albumin. The seat of this lesion is in the outer epithelial layers of the glomeruli. The author's views as to treatment are as follows: Dietetic measures in themselves are insufficient; nevertheless he would institute at the beginning of the treatment a form of rest cure and also forbid all articles of diet which might produce renal irritation. The patients are restricted to an exclusive milk and vegetable diet for a considerable period. Only after the urine has been free from albumin for a period of several weeks, were the patients gradually restored to an albuminous diet. Efforts at prophylaxis by giving a diet without fluids were unsuccessful. Aside from the discomfort produced, it was found that the small quantities of concentrated urine invariably contained more or less albumin. Energetic diaphoresis also failed. It seemed that the most favorable forms of treatment consisted of diuretic measures and good results were noted from the administration of the various alkaline mineral waters. This seems to confirm the supposition that a nephritic process is probably the cause of the trouble. He sums up his experience in the treatment of this

class of cases as follows: The kidneys must become accustomed to the demands made upon them by the muscular system and this can only be accomplished by a graduated system of diet and exercise. Too much of the latter he has found to be harmful, and constant observation for prolonged periods should be the rule.

Immunization Against Tuberculosis.—The numerous difficulties attending attempts at immunization with either human or bovine bacilli are claimed to have been overcome by F. F. FRIEDMANN (Deut. med. Woch., Dec. 17, 1903). He has succeeded in rendering guinea-pigs and other animals immune to virulent doses of tubercle bacilli by previously injecting tubercle bacilli derived from a large turtle which had died from spontaneous tuberculosis. These injections are followed by a local infiltration which soon heals without any scars, and the animals are left in good health, while they tolerate without reaction doses of human and bovine infection which would otherwise be fatal. When killed, after three months, examination showed only occasional scattered minute nodules similar to those described in other immunized animals, but without containing any bacilli. He also noted that turtles infected with turtle tuberculosis soon die with bacilli scattered through all the organs, but if previously treated with human or bovine cultures, they are uninjured by injections of turtle tuberculosis. The author is now making efforts to immunize larger animals by this same turtle culture. As the guinea-pig did not appear to be harmed, the author believes that other animals will also remain free. But, on the other hand, as the guinea-pig, which is a most susceptible animal, is so readily immunized against tuberculosis from other sources by this method, it must be assumed that the turtle bacillus possesses high immunizing power. Further developments of this method are awaited with interest.

Albuminuria as an Accompaniment of Diabetes Mellitus.—It is probable that if albumin makes its appearance in the urine in the course of diabetes, it is significant of the development of unsatisfactory conditions. It usually disappears with the establishment of more favorable signs. F. W. PAVY (Lancet, Dec. 5, 1903), from an analysis of 17 cases, concludes that there are no grounds for believing that the temperate use of alcohol in these cases is prejudicial. If not used in moderation, however, the damage inflicted throughout the system by the impairment of the kidney is decidedly grave. Albuminuria in connection with diabetes may exist for a long time without leading to any symptomatic indication of its presence. It is, therefore, less significant in these cases than in ordinary conditions of nephritis, making it evident that albumin and casts have a different signification according to the conditions with which they are associated. Experience shows that even apart from diabetes, they are met with frequently in persons of advanced age who present no other symptoms of renal trouble. That they are insignificant is often shown by the fact that time may pass without the development of further symptoms.

PHYSIOLOGY.

The Biological Function of Calcium.—In an investigation of the relation which calcium bears to the enzymatic process that results in the coagulation of the blood, L. SABBATANI (Arch. Ital. de Biol., Oct. 10, 1903) finds that calcium is present in the ionic state, and that the amount of calcium-ion sufficient to bring about coagulation is very small, much less than the total quantity of calcium normally present in the blood. This hypothesis explains rationally a large number of phenomena relating to blood-coagulation, namely, as follows: (1) All the physical causes that diminish the degree of ionization can produce incoagulability (cold, great molecular concentration). (2) All those reagents, which, like the oxalates, fluorides, and alkaline carbonates, prevent coagulation by combining with the calcium in the blood, produce this result when present even in very small doses. Upon the basis of his researches the author concludes that the coagulation of blood requires the presence of Ca-ion, whose concentration may vary between wide limits; this concentration has a minimum and a maximum, below and above which respectively the blood remains indefinitely in a liquid state. The blood will not coagulate if by means of physical or chemical reagents the Ca-ion is made to go beyond the above limits.

A Glycolytic Substance Isolated from Yeast.—That nucleohistone determines the fermentation of the monosaccharides is apparently established by the researches of A. HERLITZKA (Archives Ital. de Biol., Oct. 10, 1903). The question is then asked: Can the nucleohistones be classed among the soluble ferments? The latter are considered to be the product of living protoplasm, while nucleohistone is an integral part of protoplasm, indeed, its most highly differentiated part being an important constituent of the nucleus. It would seem that the numerous catalytic phenomena discovered within the past few years as the result of the action of nucleohistones, are to be attributed not to the action of enzymes, but to the direct action of living protoplasm. Distinguished from enzymes, these substances would be termed "plasmozymes."

Acapnea, a Result of Lowered Barometric Pressure.—A marked diminution in the carbonic acid in the blood resulting from a lowering in the barometric pressure, has been noted by A. MOSSO and G. MARRO (Archives Ital. de Biol., Oct. 10, 1903), who apply to this condition the name acapnea. The considerable variation in the content of carbonic acid following a change from the respiration of air at ordinary pressure to that of rarefied air, in a very short time, cannot, according to the authors, be explained on the basis of a simple phenomenon of physics. It must be the result of the chemical decomposition of constituents of the blood and tissues.

The Hydrolysis and Synthesis of Fats by Platinum Black.—It is now generally believed that the action of the various ferments is the same as that of the catalytic agents used in chemistry. Bredig was the first to show that colloidal solutions of gold, silver, platinum, etc., have an action similar to that of certain enzymes in splitting hydrogen peroxide into water and atomic oxygen. Numerous other chemical transformations have been brought about by finely divided metals, namely, the oxidation of alcohol to acetic acid, the decomposition of dilute oxalic acid, the oxidation of pyrogallol, the inversion of cane-sugar, etc. In a series of interesting experiments, HUGH NEILSON (Am. Jour. Physiol., Dec. 1, 1903) found that platinum black can imitate the action of lipase, the fat-splitting ferment. In comparing the catalytic action of platinum black with that of lipase on ethyl butyrate, the following facts were observed: Platinum black accelerates the hydrolysis of ethyl butyrate, as lipase also does. But the action of platinum is slower. The action of the platinum increases with the increased concentration of the platinum. This is also true of lipase. The action increases with the temperature, reaching into maximum at 50°, which is somewhat higher than the lipase. The action of the platinum is independent of the concentration of the ethyl butyrate, which seems also to be true of the action of lipase. Poisons, with the exception of sodium fluoride and hydrocyanic acid, affect the catalytic action of platinum in a manner quite comparable to their action on lipase. Platinum

black synthetizes butyric acid and ethyl alcohol into ethyl butyrate, as shown by increasing odor of ethyl butyrate and saponification giving odor of butyric acid. This synthesis is also brought about by lipase.

Effect of Water and Food on Gastric Secretion.—Most of the reported experiments upon the effect of food on the secretion of the stomach are faulty, since the food was chewed and swallowed and thus an irritation of the olfactory and gustatory nerve brought about which was responsible in part for the hydrochloric acid secreted. G. LANG (Deut. Arch. f. klin. Med., Vol. 78, Nos. 3 and 4) repeated the experiments with water, proteids, carbohydrates and fat, on perfectly healthy individuals, but took the precaution to introduce the food with the stomach-tube. He reports as follows: Water gives negative results; the expressed fluid was not at all or only faintly acid. Starch also proved an indifferent body; sugar did not bring about any appreciable acidity, but the amount of fluid expressed was larger than with starch. Whether the slightly hypertonic fluid caused a secretion of water from the stomach walls or whether the motility of the stomach was actually impeded, could not be decided. When fat was employed, the expressed fluid contained a much higher percentage of this than the ingested fluid, since water leaves the stomach more readily than fat. Probably the fat irritates the pylorus reflexly as soon as it reaches the duodenum, thus causing a partial closure of the stomach, while the water is absorbed from the gastric mucous membrane. In a case of nervous dyspepsia, where plain water gave rise to acid secretion, fats actually diminished the acid, but with butter the percentage of organic acids was high, probably owing to the fat-splitting ferment of the stomach. Gelatine, though normally acid, was expressed nearly neutral, possibly owing to an alkaline pyloric secretion. The same pyloric closure was noticed here. Proteids were found to be the only food-principles which cause hydrochloric acid secretion, though the amounts were always much smaller than occur with the usual test-meals. It follows, from all these experiments, that gastric secretion is affected more strongly by reflex stimulation than by direct irritation. The reflex stimulation is strongest, if chewing is accompanied by a pleasant sensation, as in the case of palatable food, than with pungent articles such as mustard, which are more apt to excite disgust.

Origin of Glycogen from Proteid.—The question, if proteids alone can bring about a deposit of glycogen in the liver, has apparently been solved by C. HIRSCH and D. ROLLY (Deut. Arch. f. klin. Med., Vol. 78, Nos. 3 and 4). Rabbits were rendered glycogen-free by starvation and strychnine-tetanus, after which they received subcutaneous injections of colon cultures, so that a toxic fever set in. After a certain time the animals were killed and large deposits of glycogen were found in the liver and muscles which had formed owing to increased proteid destruction.

Action of Morphine on Animal Heat Mechanism.—An inquiry to determine how morphine acts to cause the profound fall of heat production and temperature has been made by E. T. REICHERT (Univ. Penn. Med. Bull., Nov., 1903). Two series of experiments were made, one being in reference to the temperature curve in normal animals, and the other in reference to the specific actions upon the thermogenic mechanisms. The latter consisted of a number of series in which sections of the cerebrospinal axis were made at various levels, thus eliminating from time to time certain portions of the heat-producing apparatus, and thus determining by exclusion the parts acted upon. He found that morphine exerts coincidently thermodepressor and thermo-augmentor actions, the former being by far the most important; and that the thermodepressor effects may be preceded or interrupted by thermo-augmentor effects. The thermodepressor action is exerted solely upon the caudate thermo-augmentor center. The thermo-augmentor action is exerted chiefly upon the pontobulbar thermo-augmentor center, and to a very limited extent on the skeletal muscles. It was also found that morphine and codeine are direct antagonists in their actions upon the caudate center.

NEUROLOGY AND PSYCHIATRY.

Progressive Myoclonus Epilepsy.—In an interesting pamphlet, H. LUNDBORG goes into a detailed description of progressive myoclonus epilepsy, which he has made the object of special study. The disease generally begins acutely during late childhood without ascertainable cause. Girls are generally affected earlier and more frequently than boys. The first symptoms are nocturnal epileptiform convulsions which may be preceded for some time by nocturnal incontinence. After several years, during which the attacks become more frequent, myoclonic symptoms develop. In rare instances the myoclonic symptoms precede or appear simultaneous with the convulsions. The course is chronic and progressive; soon the patients will become helpless and general marasmus will appear if some intercurrent disease does not carry them off. Three distinct stages may be recognized: (1) The epileptic-tetaniform stage. Here the condition is first diagnosed as epilepsy, but soon the tetaniform character of the convulsions will be more pronounced; the patients awake suddenly and complain of a painful spasm in different parts of the body. The mildest attacks merely amount to several rapidly repeated twitchings in the extremities; the severer ones may last half an hour and may closely simulate tetany in that the twitchings are so rapid that the muscles cannot relax in the interval. Occasionally consciousness is lost here, perspiration and salivation are increased, but urine and feces are not voided involuntarily. Every manipulation aggravates the suffering, but as the attacks increase in frequency and appear almost every night, they become milder, diurnal symptoms appear and the patient enters the second, the myoclonic-epileptiform stage, which is of much longer duration, and may last decades. Tremor, fibrillary and fascicular disturbances of motility are noticed and myoclonic twitchings make their appearance, first in the upper, then in the lower extremities, trunk, neck, face, then the diaphragm and pharyngeal and laryngeal muscles, and finally the ocular muscles and sphincters. It is particularly characteristic that the severity of the disease varies on different days, and distinct cycles, lasting several days to weeks, may be noticed. External irritants of all kinds and psychical disturbances aggravate the twitchings. The patellar reflexes are usually increased, nutritive disturbances are absent, but in time a certain degree of muscular rigidity may appear. In the later periods of this stage, psychical depression is pronounced, intelligence is on the decline and the patients become stupid and capricious, and not rarely violent. The terminal stage is marked by gradually increasing decay and cachexia. The epileptiform convulsions cease entirely, the periodicity is less regular, and the patients are almost constantly in a semi-stuporous condition, interrupted only by the myoclonic twitchings. Despite all care the course is steadily downward. The etiology of the disease forms a very interesting study. Generally several members of the same family are affected, while other members often give evidence of diseased nervous systems. Thus in one family, whose records dated back for over a hundred years, eighteen cases were discovered in ten branches, yet direct transmission from one generation

to the other is not the rule. Alcohol seems to play the same prominent part as in epilepsy, for in more than half of the patients the fathers were addicted to drink. Marriage between near relatives is rather common in the afflicted families. The influence of puberty, menstruation, pregnancy and lactation has not been studied sufficiently, but the advent of puberty seems to aggravate the disease. Infectious diseases, such as syphilis and tuberculosis, probably play no part. A few complicated and atypical cases are on record, and the differential diagnosis may occasionally present difficulties. Chronic progressive chorea is generally directly inherited, it affects individuals later in life, shows no regular periodicity and the twitchings are slower and more liable to affect groups of muscles. Koschewnikow's epilepsy bears a close resemblance, but paretic weakness of the extremities, contractures and muscular rigidity do not belong to myoclonus epilepsy. Hysteria alone or complicated with epilepsy may be very difficult to distinguish; chorea electrica is an endemic disease affecting individuals later in life; it generally runs an acute course with fever; the twitchings affect only one side of the body and they are accompanied, not preceded, by epileptiform attacks. Paralysis agitans may occasionally simulate atypical forms of the disease. Lastly, Thomsen's disease may run a very parallel course, but the muscular contractions are more tonic and the mind is usually not affected. The pathology is interesting in that there are found the lesions of epilepsy in the second layer cells of the cortex, plus a maximum intensity of the same form of cell-death in the cells of the third layer. Presumably the latter changes underlie the myoclonic spasm. The two diseases have a common soil of degeneracy which is expressed in an organic cellular anomaly of the second and third layers of the cortex. This anomaly manifests itself at the supererogation of an immediate excitant, in epilepsy and myoclonus. This excitant is probably a general toxic or autotoxic agent acting in a uniform manner upon these particular cells. Since the soil for the implantation is so remarkably degenerative, the intoxication may be slight and transient, and therefore doubly difficult to detect. If thyroids and parathyroids are extirpated in animals a condition very similar to myoclonus epilepsy is induced and a thorough study of the parathyroids in connection with the disease is imperative. The treatment is very unsatisfactory, yet the suffering may be considerably allevated. The best care is always in an asylum, since relatives rarely exhibit the necessary patience. Venesection, hypodermoclysis and warm baths often cut short the attacks. The bromides and chloral are as efficient as in epilepsy, but organotherapy has proven a failure, though thymus and parathyroid tablets have not had sufficient trial. Operative removal of parts of the cortex has been tried in one case, but the patient died soon after from wound-infection.

Variations of the Syndrome of Cerebral Tumors.—Duret di Lilla (Gazz. degli osped., Dec. 3, 1903) divides the symptoms of brain tumors into prodromal, complete, attenuated, incomplete or partial, primary or secondary, delayed, or cases with reversed or irregular symptoms. There are cases also where the only manifestation of the tumor is in convulsive or epileptic crises: (*a*) Acute or early cases, complete syndrome, with a progressive course. There are usually cases at the base of the brain, central ganglia, or cerebellum or large tumors. There are exceptions to this rule. (*b*) Syndrome attenuated, incomplete or partial. In these cases only two or three cardinal symptoms of brain tumors are present. (*c*) Syndrome primary, secondary, delayed, or reversed. In these cases symptoms caused by irritation are more marked than by actual presence of a neoplasm. Local symptoms may be absent in cases where autopsy shows a large growth. An entirely different set of symptoms may be caused by the same tumor at different times. (*d*) Syndrome reduced to convulsive symptoms alone. These symptoms may be caused not only by tumors in the motor region, but by tumors of the parietal, basal, cerebral or other regions. They may be caused by very small tumors. (*e*) Syndrome of the nature of vertigo, without other symptoms. (*f*) Syndrome marked chiefly by mental symptoms or pain. The writer concludes that the usual clinical syndrome does not constitute an absolute criterion for diagnosing a cerebral tumor, but is in reality an epiphenomenon.

PEDIATRICS.

Acid Creamless Milk in Gastro-enteritis.—Since 1897 the most strenuous efforts by intestinal lavage, water diet, baths, astringents, etc., have been made by Henri de Rothschild (Le Progrès Medical, Oct. 24, 1903) and his associates to overcome the gastro-enteritis of infants. But in spite of the most devoted care the mortality up to last May was in the neighborhood of fifty per cent. At that time the treatment was changed to milk deprived of cream by centrifuging and acidified by pure cultures of the lactic ferment. From 30 to 60 cc. of this were given at each feeding. The cases treated were those of grave prognosis characterized by very profuse diarrhea, rapid emaciation, bad general condition and high fever. In a remarkably short time the temperature subsided, vomiting ceased, the diarrhea diminished, the stools becoming normal in forty-eight hours in some cases, and the weight of the infant increased. The gain in weight was most noteworthy; other children treated at the same time by the older methods showed a rapid wasting. Out of 14 almost hopeless cases, 13 recovered. The milk was prepared by Tissier and Lanzenberg of the Pasteur Institute.

Starch Digestion in Infancy.—This question has been debated pro and con by numerous authors without any agreement having been reached. A series of practical experiments for the purpose of demonstrating whether infants could really digest starch, were undertaken by H. L. K. Shaw (Albany Med. Annals, Jan., 1904). Thirty-five infants were given barley water on various occasions, instead of their regular feeding. One hundred of such barley meals were removed from fifteen minutes to two hours after the feeding. The stomach was washed out before the feeding in about one-third of the cases. The stomach contents tested with Lugol's solution showed that free starch was present in 2 per cent., erythrodextrin in 41 per cent., and achroodextrin or maltose in 57 per cent. of the tests. In the first two instances the babies were sick, and in the same infants starch conversion was found at other times. In order to determine whether the stomach contents contained any diastatic ferments, the latter were removed after a regular or barley water feeding, and added in varying amounts to a one-half-per-cent. solution of laundry starch. After being in the thermostat for an hour, the addition of Lugol's solution did not show the starch reaction in a single instance. The stomach contents removed two hours after feeding showed diastatic power. Tests to determine the diastatic powers of the saliva also showed that a partial conversion had taken place, and that both free and converted starch were present in the same test tube. It appears, therefore, that the saliva of very young infants contains a diastatic enzyme capable of converting small amounts of starch into maltose; that the diastatic action of the saliva may continue in the stomach as long as two hours after feeding, and that on physiological

grounds there is no reason why young infants cannot digest small amounts of starch.

The Value of Antitoxin as a Prophylactic in Diphtheria.—The following highly interesting statements were made by NETTER, at the recent International Congress of Hygiene at Brussels (Gazz. d. Osp., Nov. 3, 1903): At the request of the Pediatric Society of Paris over 11,300 prophylactic injections of diphtheritic antitoxin were reported, of which some were made in private practice, and many in public institutions. The conclusions drawn are to the effect that these injections confer an almost complete immunity which begins twenty-four hours after the injection had been made, and usually lasts for about one month. Those that get the disease pass through a benign, considerably modified form of it, similar to the varioloid of vaccination. Accidents attending these injections are few and of little importance, usually occurring in adults; abscesses must be accounted for by lack of cleanliness. The usual dose employed as a prophylactic was 500 units. All children of a family where there is a case of diphtheria should receive prophylactic doses of the antitoxin; this measure is of especial importance in cases of public institutions, schools, colleges, etc. Wherever there is a prevalence of diphtheria in institutions it is advisable to subject the children to monthly prophylactic treatment, as outlined above, until the epidemic is thoroughly stamped out. This should also apply to cases of measles, scarlet fever and doubtful infections; the injections here should be stronger and at shorter intervals. Löffler and Netter obtained a unanimous approval of the Congress as regards the above measures.

Treatment of Constipation in Infants.—A simple method of treatment of obstipation in infants is recommended by CLAMMAN (Deut. med. Woch., Vol. 29, No. 44), which he has employed successfully for several years. As the infant lies on his back, a medium-sized Nelaton catheter, thoroughly oiled, is introduced into the rectum. This is then worked backward and forward, and also gently twisted, inducing by this means reflex expulsive action on the part of the intestines.

Pyelitis in Infants.—Attention is called to the possibility of a primary pyelitis in infants which may be readily overlooked, as the urine of babies is rarely examined. M. HARTWIG (Berl. klin. Woch., Nov. 30, 1903) reports three cases in which the clinical picture closely resembled typhoid. The symptoms consisted of a gradually increasing fever which continually returned even after the administration of antipyretics. This could not be accounted for by anything found on repeated physical examinations, until the urine was carefully examined. This was found cloudy and full of bacilli and pus corpuscles. The treatment consisted of various antipyretic measures, and bromide of sodium to guard against eclamptic seizures. Urinary antisepsis was secured by urotropin and turpentine. A cure resulted in from three to four weeks. The author advises that in every case of continued fever in a baby, where all other sources can be eliminated, including typhoid, the urine be carefully examined microscopically. Secondary pyelitis is common enough, but a primary form is rather rare, and should always be borne in mind in doubtful cases.

HISTOLOGY, PATHOLOGY AND BACTERIOLOGY.

Pathology of the Parathyroid Gland.—Strangely enough, the parathyroid glands, though apparently of great physiological importance, have been neglected from an anatomical and pathological point of view. H. PETERSEN (Virchow's Archiv, Vol. 174, No. 3) has examined a hundred of these organs and has been able to find them in almost all cases at the middle of the posterior edge of the lateral lobes of the thyroid. Occasionally two organs were present on each side, less often only one on one side or two or three on one side and one on the other. They generally bear a distinct relation to the larger thyroid vessels and their shape varies considerably. In young individuals, the amount of connective tissue is scant and follows the vessels so that the organ may be regarded as a mass of cells divided into lobules by its arteries; but with age the amount of fibrous tissue and fat increases. The vessels enter at a slight depression, which may be regarded as hilus. The greatest importance attaches itself to the parenchyma cells which may be of two types: a large cell with well stained intercellular substance and peripheral nucleus and a smaller one with more indistinct contours and central nucleus. Excretory ducts could not be detected. After the twentieth year, a third type of cell, indicating a degenerative swelling, may occur. Hemorrhages, pigmentation, deposit of colloid, cystic degeneration and fatty infiltration are very common. Elastic fibers occur only in the larger-sized vessels, while the smaller ones seem to distend and tear very readily. As with the thyroid gland, the internal secretion seems to be colloid in nature; it is occasionally stored up and then presses the cells into duct-shaped structures. Any distinct pathological changes standing in relation with the disease of the patient, were not found, but in one case of Addison's disease the colloid deposit was especially large; in one of pernicious anemia there was complete cystic degeneration, and in a case of diabetes a pronounced fatty infiltration was present.

Localization of Hemichorea.—Occasionally an apoplectic stroke is preceded for some time by choreic movements involving the side of the body to be paralyzed, more often this phenomenon is noticed after the paralysis. It stands in close relation with hemiathetosis but has nothing to do with general chorea. D. AUFSCHLAGER (Zeitsch. f. klin. Med., Vol. 51, Nos. 3 and 4) has had occasion to dissect the brain of a patient who died of tuberculous meningitis and who had had choreiform movements in one arm for fifteen years. An old apoplectic cyst was found in the thalamus opticus to account for these. Pressure upon the pyramidal tracts could be ruled out and the long duration of the affection spoke against a purely functional derangement of the motor fibers.

Air Embolism.—The dangers following this affection are explained by L. P. WOLFF (Virchow's Archiv, Vol. 174, No. 3) as follows: The air rapidly enters the right heart where it causes a distinct sound and then passes into the pulmonic circulation, obstructing the smaller vessels. The heart will be able to overcome this enormous resistance only if a small number of capillaries contain air, and if it is not weakened by disease or hemorrhage. Air is only rarely seen in the left heart or systemic circulation; if present, it is due to post-mortem decomposition or to an open foramen ovale. If death does not set in, the air is pressed out of the vessels into the alveoli as the pressure here is least. Occasionally a few bubbles pass into the pulmonic veins and the patient may then die of embolism of the cerebral, spinal or coronary vessels. To avoid air embolism, all gaping of the veins at the root of the neck should be guarded against, and the wound should be constantly kept moist. In operation on the puerperal uterus, the Trendelenburg position must be avoided. As soon as air has entered, it must be pressed through the lungs as rapidly as possible by inducing coughing or vomiting or by giving a saline infusion through the injured vein or else an attempt must be made to force the air backward by rhythmic compression of the thorax with alternate opening and closing of the vein.

The inhalation of oxygen is also serviceable. Puncture of the right heart is an extreme measure, which will rarely do good.

Cause of Human Actinomycosis.—A distinct difference in growth is obtained if actinomycotic pus is transplanted on culture media instead of the characteristic granules; in the former case the colonies will be larger and the gelatine will be liquefied more rapidly than in the latter. As observed by K. Döpke (Münch. med. Woch., Dec. 22, 1903) the oval bodies contained in the granules will first elongate and divide. This division may repeat itself several times after which elongation takes place to be followed by segmentation into a number of short rods. The behavior toward Gram's stain is peculiar: the granules stain well, but lose this property soon after division, until they develop into rods when they again retain the dye. The club-shaped structures, which are so frequently described as characteristic, are probably not signs of degeneration, since they frequently develop and disappear rapidly in the same culture. It is more likely that they constitute spore-containing receptacles, as granules develop from them very rapidly, even under unfavorable conditions. It is much easier to find club-shaped structures in the pus from animals than from man, and the two forms of actinomyces are probably not exactly identical, unless the variations are due to the different culture-media. The tendency to calcify manifests itself also on artificial media in the form of mulberry-shaped, very hard granules, which settle to the bottom of the tube. The best medium is invariably glycerin-agar at body temperature, with or without oxygen; the cultures here are raised, amber-colored with darker and depressed center from which radiations extend to the periphery. The method of infection in man is not as clear as in animals, but since the germ has been found in the contents of carious teeth it is possible that it can be transmitted by dental instruments.

Pathology of Pertussis.—Based upon a large number of autopsies, G. Arnheim (Virchow's Archiv, Vol. 174, No. 3) looks upon whooping-cough as an infectious condition of the respiratory passages, especially the trachea, manifesting itself chiefly as a desquamative catarrh. The characteristic bacteria are easily detected in large masses in the mucus and the mucous membrane, and where the lungs are involved they also occur in the bronchopneumonic foci. The characteristic attacks are induced by the presence of the bacteria in especially sensitive portions of the larynx and trachea. They are to be looked upon as attempts to rid the system of the germs. During the course of the disease the secretion becomes more viscous, owing to the influence of pyogenic germs which also set up an increased chemotaxis of leucocytes. After the disease is over, the mucous membrane returns to its normal condition.

Organization of Blood Effusions.—A case of extensive cerebral hemorrhage of some age, observed by R. Milner (Virchow's Archiv, Vol. 174, No. 3) offered valuable material for the study of the alterations which the effused blood undergoes. The cause of the chemical changes is to be found in the surrounding tissue; its influence manifests itself slowly in the thrombus but more rapidly in the cells. The hemoglobin is first converted into hematoidin and a hemosiderin which gives no iron reaction; this may occur in the red cells or after these are disintegrated. Both principles occur in solution from which they slowly precipitate, the first as distinct crystals, the second in the form of granules with sharp edges. The disintegrating leucocytes play an active part in bringing about this precipitation, but for the hematoidin the fibrin also has some influence, and for the hemosiderin the stroma of the red cells. The remainder of both solutions saturates the strands of fibrin where part of the hemosiderin is converted into another variety of this substance containing, however, iron. The leucocytes from without have little influence upon the modification of the pigment, but the epithelioid cells are very potent, no matter whether the pigment is dissolved or not. Fixed cells of the dura, which have absorbed coloring matter, demonstrate the same changes. The hematoidin is rapidly dissolved out of the cells and carried into the blood-stream but the second form of hemosiderin is more permanent.

Glycogen Reaction of Leucocytes.—The blood examination in a large number of cases has convinced J. Sorovowitsch (Zeitsch. f. klin. Med., Vol. 51, Nos. 3 and 4) that the presence of the glycogen reaction in the leucocytes is not an absolute proof of suppuration, though it makes the existence of an abscess somewhere in the body probable, if other clinical symptoms are present, provided the patient is not suffering from pneumonia. A positive iodine reaction was also found with coprostasis, on account of the intestinal intoxication accompanying this, with small circumscribed carcinomata and in other intoxications with local pains. In blood diseases the test is of no importance but it will often aid in distinguishing between rheumatic and gonorrheal arthritis, since always negative in the former and positive in the latter. A positive reaction is also common in myxedema and Addison's disease, which points to the imperfect neutralization of some toxin in the circulation. Glycogen was detected more frequently in the cells of exudates and pus than in the blood, even if the irritant was non-bacterial and it seems likely that the protoplasm of the leucocytes undergoes a distinct change as soon as they leave the vessels. The reaction can be artificially created by injecting all kinds of toxins and irritants into the blood of animals. The phenomenon is probably a form of degeneration; every living cell is able to convert proteid into glycogen and this into glucose by means of a special ferment. When an irritant is present, the ferment is paralyzed or destroyed, so that the glycogen remains stored up in the cells and is lost to the animal economy. There are many different ways of demonstrating iodophile leucocytes; in the simplest one thin cover-slips are prepared and then immersed for three minutes into iodized gum containing one gram of iodine, three of iodide of potash and 60 of gum arabic to one hundred of water. Canada balsam must be avoided.

The Morphology and Chemistry of Fatty Degeneration.—That fatty degeneration is due to an infiltration of previously injured cells is the claim made by H. Ribbert (Deut. med. Woch., Vol. 29, No. 44). He believes, from the results of his observations, that the fat enters into normal cells and accumulates as deposits of fat, forming the adipose tissue, whereas when it enters into pathological cells it produces fatty degeneration. The two processes may thus be regarded as a physiological and a pathological fatty infiltration.

Development of the Islands of Langerhans.—A careful study of this development has been carried out on the pancreas of 21 human embryos by R. M. Pearce (Univ. Penn. Med. Bull., Nov., 1903). He finds the differentiated cells, characterized by a rich, finely granular, eosinophilic protoplasm, lie as small round or oval masses in direct continuity with the cells of the tubule. Later the attached portion becomes constricted, and, lengthening, forms a stalk-like, solid process of cells connecting the island with the acinus. At this period a few entirely isolated islands are present. A separation takes place and is apparently brought about by the pressure of the investing connective tissue. Vascularization has now occurred. Later on the cells be-

come arranged in columns and a fine reticulum is observed. The rapidly forming glandular structures finally surround the islands, which then occupy the centers of the lobules. In syphilitic pancreatitis of the newborn, a condition in which the normal development of the pancreas is arrested by a rapid proliferation of connective tissue, confirmatory evidence of this mode of development is supplied by the presence of solid processes of cells connecting the islands and acini. The demonstration of the differentiation and final independence of the islands of Langerhans, as here given, offers an anatomical basis for the theory, so strongly supported by pathological and experimental observations, that the islands have a physiology independent of the glandular portion of the pancreas.

Differentiation Between Typhoid and Other Intestinal Germs.—O. LENTZ and J. TIETZ (Münch. med. Woch., Dec. 8, 1903) recommend the following bacteriological method for suspicious stools: The feces are mixed with double the amount of physiological salt solution, until a homogeneous mass results; 0.1 to 0.2 c.cm. are then distributed evenly upon a dish of agar, containing malachite green in the amount of 1-6,000. Colon bacilli do not grow upon this medium but typhoid bacilli and certain alkali-producing bacteria readily develop to colonies resembling dewdrops. The spatula used for spreading the germs is also passed over the surface of two litmus-lactose-agar plates which are examined after twenty hours. If no typhoid colonies are then found upon these, four or five suspicious colonies of the green plates are tested with highly agglutinating serum. Should this also give negative results, the entire surface of the green plate is washed off by means of 2 c.cm. of broth and a loopful then distributed over another blue plate. After sixteen to twenty hours, typhoid germs can then be readily detected, even if the stool contained only few. The green agar also forms an ideal culture medium for the paratyphoid germ.

An Effort to Produce an Antibody from the Blood Serum of Cancer Patients.—The following experiments were made by C. S. ENGEL (Deut. med. Woch., Vol. 29, No. 48) for the purpose of producing antibodies without anti-alexins. Ten to fifteen cubic centimeters of blood were drawn twice a week from each of two subjects afflicted with inoperable cancer of the stomach, and the resulting serum was injected into rabbits. The serum was heated to 58° C. before injection, in order to eliminate the alexins. The serum from the rabbits thus treated was injected into the cancer subjects together with a further supply of alexins in the form of normal serum from healthy subjects. Tests of the serum in vitro indicated that antibodies had been generated in only one of the rabbits; in that from the other animals they were negative. The author claims that one of the patients showed considerable improvement after this serum treatment and was able to swallow solid food. The disease continued its course, however, and the patient died in four months. The other patient died in about two months without having showed any signs of improvement. The author believes that serumtherapy based on injections of cancer tissue is more promising than that based on injections of serum. Other experiments also indicate that the prospects are much better for the production of an effective animal serum by injection of human blood serum from subjects with constitutional disease other than cancer.

GENITO-URINARY AND SKIN DISEASES.

Preventive Treatment of Syphilis.—Whether it is possible to abort syphilitic infection after the initial lesion has appeared is considered by many to be still an unsolved problem, for it is yet an undecided question whether the chancre is a strictly local lesion or whether the general infection has already taken place when this appears. E. HOLLÄNDER (Berl. klin. Woch., Nov. 16, 1903) has recently published his observations on a series of 59 cases which he has treated and kept under continual surveillance. He brought about the destruction of the chancre by means of the Pacquelin cautery, never bringing the glowing point in actual contact with the lesion. He claims that by this means heat rays penetrate much more readily and diffusely into the tissues than when the cautery point itself enters the skin. In the latter case, the instrument merely cuts and the effect is mechanical rather than thermic. Of the 59 cases operated upon, later syphilitic lesions developed in 12, while some of a more doubtful nature appeared in 3 others. The remaining cases were free from further symptoms for varying periods of from 2½ years to six months. Five of these patients married, and in no case was the wife infected—some even bore healthy children. It was also found that in a number of instances where swelling of the adjoining lymph-nodes was present, the latter subsided. Another point which the author determined was the difference in the behavior during cauterization of the specific and non-specific lesions. If, after cauterization of an ulcer, without bringing the glowing into actual contact with the sore, the base of the latter be scraped with a sharp spoon, not a bit of tissue can be scraped away if the lesion has been a syphilitic one, and no bleeding results. In the case of a non-specific ulcer, however, the entire base of the ulcer can be readily scraped away and bleeding follows—no actual induration is present. The latter also heals up very quickly, while cicatrization in the chancre may take several weeks. In those cases where further specific lesions developed, the entire course of the disease was found to be much less severe than in ordinary cases and the author believes that destruction of the primary sore has a marked beneficial influence. The proof of a definite healing also seems evident by the fact that in a few cases the patients again became infected with a hard chancre.

Treatment of Skin Diseases by Light Rays.—A series of 111 cases of various skin diseases which have been treated by the Finsen or the Roentgen rays is reported by J. F. SCHAMBERG (Am. Med., Dec. 19, 1903). The former was used in 15 cases, and he believes that it is the best-known treatment for lupus vulgaris. In the erythematous form he has seen some improvement, but no cures. When the lupus nodules are ulcerated he finds that the Roentgen rays should be given preference over the Finsen rays, when the mucous membranes are affected, and also in hypertrophic and vegetative forms of the disease. He comes to the same conclusions as other observers as to the limitations of the X-ray in cancer of the skin. The X-rays were also found extremely valuable in acne and brilliant results were obtained even in long-standing cases. In eczema the X-rays were found to relieve the itching and in effecting a disappearance of the eruption. In psoriasis the effect was only temporary and relapses are not less common than under other methods of treatment. Benefit was also found in addition in other dermatoses, sycosis, lichen planus, ringworm and favus, tuberculosis of the skin, blastomycetis and others. He believes that the liability to the production of a burn, with ordinary measures, is extremely slight.

Inoculation of Anthropoid Apes with Syphilis.—Attempts to confirm the experiments of Metschnikoff and Roux in this field have been made by O. LASSER (Berl. klin. Woch., Dec. 28, 1903). He inoculated a male chimpanzee with virus from a man who presented the initial lesion of syphilis on his arm. Multiple inoculations were made on the lips and the forehead which

healed promptly within forty-eight hours. In two of the localities—above the eyebrows—lesions appeared in two weeks, which, in their form, color, indurated edges and central ulceration, strongly suggested the primary syphilitic sore as found in man. Within a few weeks a characteristic papillary eruption also appeared in the palms and soles, around the anus and on the forehead, from which the hair also began to fall out. The cervical lymph-nodes then became enlarged. The author does not claim that the evidence is positive that the disease may be transmitted from man to the ape, and that in this case the picture is that of an abortive or weakened form of syphilis, gauged by the standards adopted for man. It is hardly to be expected that the virulence of the disease may be sufficiently increased to permit its transmission from one animal to another. The rarity of the material and the prevalence of tuberculosis among apes in captivity are unfortunately marked hindrances to extended experiments. Sections made from the initial lesions show an endo- and peri-arteritis of the superficial vessels, with a thickening of the walls and infiltration of the adventitia, similar to that in the initial sclerosis seen in man. The article is illustrated with some very interesting photographs.

Asepsis in Catheterization.—An ideal lubricant for catheters and sounds, recommended by L. Casper (Deut. med. Woch., Vol. 29, No. 46) consists of a mixture of glycerin, water and tragacanth, together with mercury oxycyanate 1 in 500. This does not irritate the urethra, renders the instruments very smooth and slippery, is readily soluble in water and dissolves as soon as the instrument is inserted into the bladder, without obscuring the view through the cystoscope. In place of boric acid for washing out the bladder he prefers mercury oxycyanate, 1 in 5,000. This is non-irritating, does not injure the instruments, and although not a strong antiseptic, is yet sufficient to inhibit the growth of microbes. His method of sterilizing catheters and cystoscopes is as follows: The parts are rubbed with three gauze sponges dipped in tincture of green soap, using each one for a minute. The instrument is then wrapped in a compress impregnated with the same material and kept in this until needed. Whatever parts can be removed are boiled for five minutes.

Prevention of Iodism.—This is the effect of the iodized alkalies suddenly flooding the organism and pouring out through the mucous membranes. F. Lesser (Deut. med. Woch., Vol. 29, No. 46) believes that this afflux of alkali is what causes the catarrhal condition in the mucous membranes and leads to iodine intoxication. He suggests as a prophylactic measure that the iodine salts be administered in a mucilaginous vehicle in order to render absorption more slow and gradual. In some cases it may be advisable to give the iodine per rectum where absorption is also slower. Another prophylactic measure is to use the iodine in the form of iodized fats or the injection of iodipin. In cases of pronounced idiosyncrasy, the latter may be used at first in small injections in order to accustom the organism gradually, and then the internal administration may be gradually substituted.

EYE, EAR, NOSE AND THROAT.

Etiology of the Hyperplasia of the Pharyngeal Tonsil.—From a consideration of the most recent views advanced, the following conclusions as to the origin of this condition are proposed by T. J. Harris (Am. Med., Jan 2, 1904): The first claim is that the pharyngeal tonsil possesses a distinct function. This function is of the nature of a defense against the entrance of bacteria and consists in a certain irrigation of the tonsil surface by a lymph stream loaded with lymphocytes. This protection function carries with it the inherent qualities of the tonsil to enlarge on the slightest irritation for the affording of further powers of defense. This inherent tendency of the tonsil to enlarge is further seen in the frequent recurrence of the tonsil after removal. Strictly speaking, he claims that such enlargements are not a pathological, but a physiological process.

Subconjunctival Injections in Ophthalmic Therapeutics.—C. S. Bull (Trans. Am. Ophth. Soc., 1903) reviews the extensive literature of this subject, and arrives at the following conclusions from his own experience: That the efficiency of the various solutions injected beneath the conjunctiva—sodium chloride, sublimati, mercuric oxycyanide and hetol, all of varying strengths, cannot be ascribed to the increased local acceleration of the lymph currents, nor to the antiseptic action of the remedies employed, since the presence of such processes cannot be demonstrated in the tissues of the eye following the injections. The chief change seems to be in the composition of the aqueous humor, which is said to become richer in albuminoids, in combination with which there may be an appearance of certain protective substances, as is believed to be the case in the blood. Sodium chloride and mercuric oxycyanide solutions were of little value in keratitis, uveitis, detachment of the retina and panophthalmitis. Hetol or sodium cinnamate in a 1-per-cent. aqueous solution seemed to be of benefit in acute inflammations of the uvea, in hastening the process of absorption, it was apparently of no use in chronic cases, notably in scleritis, nor in two cases of tuberculous disease of the iris and choroid. In several cases of orbital cellulitis of an infectious character, however, subconjunctival injections of a sublimate solution (1-1,000) did exert a very favorable and unusually rapid effect in hastening the suppurative stage, in reducing the dense infiltration of the orbital cellular tissue, and thus aiding in restoring the circulation to the strangulated parts.

Possible Etiological Factor in Tobacco-alcohol Amblyopia.—G. E. de Schweinitz and Edsall (Trans. Am. Ophth. Soc., 1903) attempt to throw some light on what the possible poison may be which produces one or the other of the many changes which have been described by many authors in the optic nerve fibers, or the ganglion cells of the retina, and which manifest themselves by the clinical symptoms. Horner long ago, and de Schweinitz in 1900, suggested that the disease depended on a species of auto-intoxication, and the investigations of Sachs and Casey Wood indicate "that certain stomachic toxins are capable of causing in animals blindness, probably of the type now under consideration." The details and results of seven cases do not lend themselves to an abstract. Suffice it to say "there were evidences of a marked disturbance of digestion or of metabolism, or of both." The authors continue: "This view is entirely in consonance with the results of investigations concerning the manner in which other toxic effects of alcoholism are produced, and it also accords with our knowledge of the effects of some other chronic poisonings. Enlargement was easily recognizable in three of these cases, also some tenderness of the liver, and all had marked urobilinuria in addition to the evident disturbance of the alimentary tract. In certain cases the improvement in vision corresponded to the disappearance of the morbid condition of digestion.

Tobacco Nerve Deafness.—Wyatt Wingrave (Ann of Otol., Rhinol. and Laryngol., Sept., 1903) gives the results of his observations of 17 cases as follows: (1) That they were all well-marked cases of nerve deafness (unattributable to other causes) occurring in heavy smokers; (2) that the loss of low tones in 50 per cent. suggests an auditory equivalent for a recognizable ocular lesion; (3) that the disease was symmetrical; (4) that

there was impairment of color sense in 8 of them, and definite scotoma in 4 cases; (5) that 80 per cent. showed marked improvement on abstinence from tobacco, supplemented by drug treatment; three were cured.

Ocular Complications of Scurvy.—The external diseases of the eye following scurvy, such as hemorrhage beneath the conjunctiva and keratitis, have been more frequently described than the affections of the deeper parts. This is probably because epidemics of scurvy were more frequent during the pre-ophthalmoscopic days when deeper lesions of the eye were not recognized. WEILL (Zeitsch. f. Augenheilk., May, 1903) examined the eyes of 61 prisoners with scurvy, and found that three had marked optic neuritis and two retinitis. Except for one case of neuritis in a man of sixty years, which passed into atrophy, all recovered with normal vision under treatment directed to their general condition. It is striking that in none of these 61 cases was there any external ocular sign of the disease, while in another epidemic FIALKOWSKY (Centralbl. f. prakt. Augenheilk., 1880) found only hemorrhages of the lids and conjunctiva and keratitis.

Antitoxine Treatment of Hay Fever.—For several years Prof. Dunbar, of Hamburg, has been experimenting with a proteid substance which he has isolated from the pollin of rye, wheat, and other gramineous plants, and which, when applied to the nasal mucous membrane of a person subject to hay fever, causes all the symptoms of that disease. To secure an antitoxin he injected this substance into animals and after large doses had been thus injected he found that the blood from these animals exerted a marked effect in allaying all the symptoms of hay fever. Good results were obtained early this summer by Dr. Emil Mayer in several cases when treated by this antitoxin, and A. W. MACCOY (N. Y. Med. Jour., Nov. 21, 1903) now reports the results which he obtained upon 15 cases belonging to the late summer type of hay fever. He says that the effect was so promptly manifested, the relief so complete, and the result so permanent for this season, that it appears really marvelous. Thus far it has not been demonstrated whether there are several kinds of toxins causing these disturbances, but it is probable that there are, and that more than one kind of antitoxin will be required to cure all cases of hay fever.

Eumydrin, a New Mydriatic.—This lately devised product has been subjected to practical clinical tests by LINDENMEYER (Berl. klin. Woch., Nov. 23, 1903). This preparation is made from atropine, the chemical composition of the latter being changed to such an extent that its action on the central nervous system is entirely done away with, while the effect on the peripheral nerves remains. The toxicity of the new drug is claimed to be fifty times less than that of atropine itself, and in no case were any unpleasant after-effects observed. Solutions of various strengths were employed, from 1 to 10 per cent. The author believes that the drug is a valuable addition to the materia medica, producing mydriasis and paralysis of accommodation in a shorter time than is possible with atropine, although the paralysis is of somewhat shorter duration. It was also found to be efficacious in weak solutions to combat irritation produced by foreign bodies, phlyctenulæ, etc. With the strong solutions it was possible to break up fresh synechia after two or three applications. Another point demonstrated was that in those cases where on account of some idiosyncrasy on the part of the patient it was necessary to interrupt the continuous employment of atropine, eumydrin proved a very efficient substitute.

Shortsightedness in School Children.—In concluding his very instructive article on the examination of 200 school text-books from a sanitary point of view, A. RAMMUL (Russ. med. Rundschau, No. 14, 1903) draws particular attention to the fact, as substantiated by many prominent investigators, that shortsightedness in children either originates or develops in school. The chief causative agency therefore is to be found in too prolonged reading, writing and drawing, whereby accommodation as well as convergence are greatly fatigued. Undue strain of the muscles of accommodation causes an active hyperemia, the return flow of the venous circulation is greatly hindered, there is an increase of the intra-ocular pressure and the sclerotic is gradually stretched. Too strong convergence works even greater harm for the eye in various ways. It must also be observed that in some of the children shortsightedness is hereditary and they become affected so much sooner than their healthy comrades. In addition to the above cause producing shortsightedness, mention must be made of poor or insufficient lights with which many school buildings are supplied; the same may be said of unhygienic school furniture. As regards the influence of books on the eyesight the author insists that paper should not be polished, for under artificial light a polish on a paper prevents the eye from seeing well and necessitates moving the book to and fro, as well as frequent changes in the position of the head. Again, the paper should be thick enough to prevent the printing of the next page from intruding itself upon the reader's eye. Although a few authors recommend yellow paper, the majority speak in favor of white, for the contrast between the print and the paper is so much more striking the whiter the paper.

Rupture of the Sclerotic in a Staphylomatous Eye.—Ruptures of the sclerotic are comparatively rare, and are but seldom mentioned in ophthalmological literature. In the case described by L. M. FRANKEL (Prak. Vrach, Oct. 11, 1903) there appeared post-traumatically a severe hemorrhage from the left eye, which was soon controlled by the author by pressure on the eyeball. Examination revealed a complete staphyloma of the cornea, at the external canthus superiorly there was a rupture of the sclerotic of 8 to 9 mm. long with smooth even edges. The patient has had the staphyloma for over fifteen years. He was advised to undergo the operation of evisceration of the eyeball, but he consented only on the fourth day after the occurrence of the trauma. The operation was performed under chloroform after Arlt's method, the only difficulty encountered was in the fact that the eyeball was soft and contracted. The postoperative course was uneventful, and on the twelfth day patient left hospital, and was able, six weeks later, to return to his occupation, that of a packer.

THERAPEUTICS.

Calomel in Pneumonia.—The use of calomel in pneumonia has been reported and recommended favorably for some time past by C. BERTAZZOLI (Gazz. d. Osp., Nov. 15, 1903), and his present investigation is based on an experience with six cases. He does not consider the drug as specific, but is quite certain as to its beneficial effect in this disease. The remedy should be administered in generous doses and should be accompanied by such other drugs as provoke energetic peristalsis, so as to procure its complete elimination from the organism. Thus a double advantage is gained: The calomel is permitted to exert its good effect, and is at the same time not allowed to be absorbed by the system. The author prefers to administer it together with scammony, because they are both compatible, and also because of the latter's action on the intestines. The effect of calomel is principally that of an antipyretic, and at the same time it seems to cut short the further spread of the inflammatory process. The author describes its action as that of an intestinal derivative, and as he is convinced that the intense headache of pneumonia is

largely due to cerebral congestion provoked by the obstruction of the lesser circulation, as conditioned by the state of the lungs, calomel depletes the congested area by driving the blood to another portion of the body. With the headache there disappears rapidly the delirium, and the temperature falls and stays lower than it was before the administration of the drug. In calomel we possess one of the most energetic drugs in our armamentarium: It is an efficient diuretic, exerts an undoubted effect on the vasomotor system, is an active purgative, and a reliable disinfectant.

Infantile Eczema.—The following is applied morning and evening by Comby (Le Progrès Médical, Nov. 28, 1903):

℞ Acidi salicylici ..... 3.0 (gr. xlv.)
Zinci oxidi ..... 3.0 (gr. xlv)
Adipis lanæ hydrosi .....10.0 (℥ iiss.)
Petrolati .....20.0 (℥v.)

In addition he powders the regions with

℞ Acidi salicylici ..... 1.0 (gr. xv.)
Amyli
Talc
Lycopodii .....aa 20.0 (℥ v.)

Treatment of Epilepsy.—M. Laufenauer (La Méd. Moderne, Oct. 21, 1903) recommends the double bromide of rubidium and ammonium in the treatment of epilepsy; he has seen decidedly better results with this salt than with other bromides. The action is in the main the same, since the rubidium does not exercise any specific effect. The daily dose is four to seven grams; four to five grams given at night is an excellent hypnotic.

New Nutrient Enema.—This nutrient enema is recommended by A. Schmidt (Münch. med. Woch., Nov. 24, 1903), and is of the following composition: Dextrin, 50 gme. (2⅔ ozs.); Nährstoff Heyden, 20 gme. (⅔ oz.); solution sodium chloride 0.09 per cent., 250 c.c. (8 oz.). This is filled into sterilized glass tubes which need only be placed in warm water before use. Each enema corresponds to 287 colories. If the rectum is washed out several hours after an enema is given, only traces of its ingredients can be detected chemically, since absorption is almost perfect without irritation of the rectum.

Modification of the Toxicity of Poisons by the Addition of Non-poisonous Substances.—E. Lesné and C. Richet (Arch. Internat. de Pharmacodyn., Vol. XII, fasc. III and IV) find that by adding chloride of sodium to certain poisons, such as iodide of potassium, chloride of ammonia and cocaine, given orally or by intravenous injection, their poisonous properties are considerably reduced. Urea and the sugars act similarly, but not to the same degree. In mice, salt also diminishes the toxicity of strychnine, if it is injected half an hour before the alkaloid. The toxicity of urine is also lessened, but that of its alcoholic extract increased. It is probable that the animal cells, when saturated with chloride of sodium, are unable to take up as much poisonous substance as normally. The infrequency of uremia in patients with marked edema finds a ready explanation since it has been shown that retention of chlorides in the system is the cause of the edema, for the cells, already saturated with salt, do not so readily fix the urinary poisons.

Poisoning with Nitrites.—In poisoning warm-blooded animals with nitrites some will develop anesthesia, narcosis, somnolency and apathy, while others will die in most severe convulsions. E. Harnack (Arch. Internat. de Pharmacodyn., Vol. XII, fasc. 3 and 4) believes the latter symptom is not due to the nitrite itself, but to ammonia, which is always formed if larger doses of nitrite are given. The specific action of nitrites is due to a rapid and almost complete reduction in the system, manifesting itself by the appearance of methemoglobin and by the absence of nitrites in blood and urine soon after ingestion. In small amounts the cause of death is the withdrawal of oxygen alone; in larger doses, the reduction products, among which ammonia is the most important, are fatal also. There are few organic substances which are so intensely toxic as the nitrites, since death may follow in fifteen minutes.

Tobacco Smoking.—Besides nicotine, tobacco smoke contains nicotianine, collidine and other pyridine derivatives, acids, resins, carbon dioxide, prussic acid and ammoniacal salts. Two drops of nicotine placed on a dog's tongue produce in succession efforts to swallow, great weakness, convulsions, and death, in less than a minute. Eight drops will kill a horse. Tobacco contains from two to eight per cent. of nicotine, and Le Bon has determined that though most of this is changed in smoking, it appears as other pyridine bodies which are just as poisonous. Petit (Le Progrès Médicale, Nov. 28, 1903) finds that these bodies do not condense much in the warm mouth, so are mostly exhaled, therefore the physiological effect of ordinary smoking is not a marked one. Susceptible persons may, however, be much affected by breathing the air of a room in which there is much tobacco-smoke. The action of nicotine, as is well known, lies between that of the bromides and digitalis. It soothes the nervous system, but causes a powerful and rapid contraction of the vessels, and a rise in blood-pressure. Among its dangers, therefore, one of the best known is angina pectoris, perhaps due to spasm of the coronary arteries. Through prolonged use it promotes the development of arteriosclerosis. It is a habit-drug like opium, cocaine and alcohol, and its devotee loses the force of will necessary to stop the habit, though he knows it is harming him. The smoking acts also in depriving the smoker of oxygen, for the burning tobacco develops carbon dioxide and the red blood corpuscles do not form their full amount of oxyhemoglobin. In small doses the respiration is accelerated, in large dose depressed. There is apparently no bactericidal action on any microorganisms in the lungs. One of the first effects of an overdose is nausea, and prolonged smoking is a distinct factor in the production of digestive troubles.

Quantitative Determination of Pepsin.—Compared with the accurate methods we possess to determine the amount of acid in the gastric juice, the estimation of pepsin, though almost equally important, is more difficult, as hitherto impossible by volumetric means. F. Volhard (Münch. med. Woch., Dec. 8, 1903) finds that pure casein is readily precipitated by means of sodium sulphate, but if digested with pepsin, the amount of precipitate will gradually become less. The filtrate will turn more acid as the casein is peptonized and titration will give a ready index of the amount of pepsin present. One hundred cubic centimeters of a solution containing 100 grams of casein in 1,760 c.cm. of water and 140 c.cm. of normal hydrochloric acid, are diluted with gastric juice and water up to 300 c.cm., and kept at 40° C. The casein is then precipitated with 100 c.cm. of 20-per-cent. solution of sodium sulphate and finally the acidity is determined in 200 c.cm. of filtrate. The amount of juice used and the time of digestion form the figures for a mathematical formula which admits of ready calculation.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

THE POSSIBILITIES OF GASTRIC SURGERY.

THERE is an untrodden tundra in which diagnosticians must wander for many years before some satisfactory position in the rational care of gastric diseases is reached.

Dr. John B. Murphy, in the *Annals of Surgery* for December, writes that at the present time the surgical diseases of the stomach which are brought to the surgeon's notice, may be classified as follows: (1) Gastric carcinoma, (2) gastric ulcer, (3) pyloric obstruction, (4) pyloric retention, and (5) gastro-duodenal or pyloro-duodenal lesions. "If surgery," he says, "is to accomplish for the stomach all that it is capable of, the frequency with which the surgeon deals with the stomach must be for lesions in substantially the reverse order. If the first three of this reversed classification be early and properly treated from a surgical standpoint, the surgeon will be consulted very much less frequently for carcinoma of the stomach. Thirty-five per cent. to 45 per cent. of all carcinomata occur in the stomach; from one to three and a half per cent. of all deaths are caused by this disease."

Dr. W. J. Mayo, of Rochester, Minn., has shown a mortality of only 15.5 per cent. in 109 cases of carcinoma of the stomach. This, from a purely technical standpoint, is a remarkable record and shows to what a degree of perfection the art of mere removal of the growth has been brought. The final results, however, even in these cases, are profoundly discouraging. Even to the most hopeful they show that surgery, under the present limitations, has reached the bourne beyond which it cannot hope to pass. Improvement in final mortality rates must come either from a protection of the individual from cancer-producing conditions, or from pronounced improvement in our ability to diagnose the early stages of the disease.

Dr. Murphy in his characteristically urgent and appealing style, forces the blunt, but as yet imperfectly recognized truth that there is a distinct cancerous symptom complex, which in a post-mortem review of the case can almost invariably be traced. This complex is not, in his own words, "manifested as a thunderbolt from a clear sky," but is characterized by a special train of gastric symptoms that have existed in many cases for years. Irritations and retentions in the stomach play the same rôle in the production of carcinomata here as the pipe on the lip, the gall-stone in the bladder, the feces in the colon. What are the symptoms, he asks, which manifest themselves after the penetration of the basement membrane by these erratic epithelial cells? Do we, in other words, recognize the transition from precancerous conditions to cancerous?

Based on the reports from Mayo Robson's clinic, at which 101 cases of posterior gastro-enterostomy were done with but 3.9 per cent. mortality, and 20 cases of pyloroplasty without a single death, it is extremely conservative to say that exploratory operations on the stomach are practically danger free. If 100 cases showing symptoms of very slight pyloric retention could be operated upon, an exploratory laparotomy for diagnostic purposes could be done, a large longitudinal gastrotomy with subsequent inspection of the gastric mucosa would be possible with a likelihood of death in but perhaps a single case. If the hundred cases so treated were on the other hand left either to themselves, the ultimate mortality would be many times greater. Mayo Robson concludes that an exploratory operation must be performed early in order to permit of a sufficiently radical operation being done to make such treatment worthy of execution.

Von Milkulicz has estimated that four or five per cent. of the race suffer from gastric ulcer and one-fifth die as the result of these gastric ulcerations. Carcinoma may then be considered as proved in many cases, to be due to a subacute

irritation of normal or cicatricial epithelial surfaces. Retention is undoubtedly a very important etiological factor in causing irritation, not alone by the mechanical stimulus of the retained food particles, but by the chemical etching of the part, by the acids of decomposition.

With such men as Mayo, Mikulicz, Murphy, Czerny, Mayo Robson and Moynihan, urging the profession to make use of exploratory laparotomy in doubtful cases of gastric disease, is it not time that more general heed be given to their counsels? They have demonstrated we believe without the possibility of error their ability to consummate with almost no mortality the most profoundly difficult gastric operations. Five per cent. of all people have gastric ulcers. A large but unknown number of these cases develop carcinoma. Welch states that 3.5 per cent. of all deaths are caused by this disease. Can any impartial judge hear the testimony of these men and yet decide that the course at present adhered to by the majority of the profession is not at variance with the best interests of the community?

TYPHOID FEVER.

The *Practitioner* for January is devoted entirely to a consideration of typhoid fever. From remote quarters of the globe, as well as from England and America, over a dozen eminent physicians have united in discussing the occurrence, treatment and prophylaxis of what has well been termed the "ubiquitous" disease. All join in emphasizing the need and value of advanced sanitary precautions as the only means by which the disease may be held in check.

From the Far East we learn that, contrary to the former belief, typhoid fever is a common disease in India; natives and newly arrived Europeans frequently are sufferers. The natives of Egypt seem to enjoy immunity. Typhoid prevails in China chiefly among foreigners who import the disease into the country. The Chinese, unlike the Egyptians, are plainly susceptible to typhoid, but they seem to be protected by their habit of avoiding milk and the use of unboiled water for drinking and culinary purposes.

The typhoid fever which occurred among the British troops in the South African war is believed to have been due largely to impure water supplies, absence of sewerage systems, camp infection, flies, dust, and the want of such sanitary protection as is commonly afforded in cities. It is likely that all great wars will be notorious for typhoid fever, unless a complete sanitary administration can be formed to deal more adequately with the enteric fever problem than has been seen in the field in the past. A hopeful outlook toward better results is afforded by the fact that the sanitation of British camps is in the future to be entrusted to a newly created Sanitary Officer of the Royal Army Medical Corps.

Although municipal sanitation has well-nigh banished typhoid fever from some cities, it is significant to note that it does occur sporadically even in London. The small number of cases there is ascribed less to the water and milk supplies than to infected oysters and other shellfish and to what is termed "contact." By contact is meant the transmission from person to person in households, through carelessness in handling infected articles and destroying the germs of the disease. There seems little doubt but that typhoid fever spreads to a far greater extent in households than is commonly believed, a large number of instances of such transmission being available.

If typhoid is to be suppressed, it is essential that all avenues of transmission be recognized and rigidly closed. This means that established scientific facts must be acknowledged, whether they seem to agree with a former belief in the etiology of the disease or not. While no epidemic disease can be more easily controlled and prevented than typhoid, few are capable of creating greater ravages in houses, streets, hospitals, camps and cities.

Something has been done to afford individual protection from typhoid fever by the use of antityphoid inoculation, or, as it may properly be termed, vaccination. The results which have been accomplished in the South African war with antityphoid inoculation appear to have been excellent. The immediate effects of vaccination are extremely unpleasant, but for soldiers and others who expect to be especially exposed to infection, the uncomfortable consequences which temporarily follow vaccination should be more than offset by the permanent benefits afforded.

The present tendency in the treatment of typhoid is toward greater attention to the individual case, and the substitution of simple methods of diet for drugs. The watchword in the typhoid wards of Johns Hopkins Hospital is "More water." It is usual at this institution to urge upon patients about as much cold water as they can be prevailed upon to consume. The immersion bath is standard treatment; it is customary in Osler's wards to tub the patient every three

hours when the temperature is 102.5° F. or over, but more than seven baths per twenty-four hours are never given. The first bath should be 85° F. and each succeeding one 5° F. lower until the most suitable point is reached. Patients are never permitted to walk to the tubs.

Complications in typhoid fever, and correct methods of nursing and surgical treatment, are becoming more and more generally understood and practised. Rigors, apart from any recognizable complication, while alarming, need not be considered dangerous. It is imperative that the diagnosis of perforation should be made at the earliest possible moment, in order that surgical treatment may be resorted to without an instant's loss of time.

The nature of typhoid fever is coming to be recognized as a special septicemia, whose particular locus is in the intestines. Numerous differences exist among the forms which the disease takes, and it seems desirable to divide it with reference to the specific organisms whose products cause the pyrexia. One of the most clearly recognizable differences from standard typhoid is called "paratyphoid" or "paracolon" fever, a disease which resembles typhoid in its clinical course and main characters, but which is caused not by the *Bacillus typhosus*, but by another member of the great colon group to which this organism belongs. Owing to the widespread occurrence of both typhoid and paratyphoid bacilli, the Widal test of blood for diagnosis should be made not only with the regular *Bacillus typhosus* but with the bacillus of beta paratyphoid as well.

ANNUAL MEETING OF THE STATE MEDICAL SOCIETY.

The feature of the ninety-eighth annual meeting of the Medical Society of the State of New York was the adoption of the agreement which had been reached by the Joint Committee of Conference appointed by the State Medical Society and the New York State Medical Association for the purpose of bringing about the consolidation of the two organizations. The unanimous vote on the resolution followed by prolonged applause practically proclaimed the end of medical disunion in New York State—we hope forever. There is still of course the formality of having the State Medical Association adopt the committee's report, but of that there seems no reason for doubt. An unfortunate division that has lasted twenty years is thus brought to an end and the medical profession of the great Empire State will very shortly be able to get away from the undignified position it occupied and which did so much to impair its influence.

The first proof of the new and more satisfactory status of the profession of the State came when without any hesitation or demurrer the two houses of the legislature passed the enabling act for union within a few hours of its introduction, which the Governor as promptly signed. In the past New York legislators have promised that when the united medical profession of the State would come to them for legislation there would be no procrastination in granting it. The present legislature has fulfilled this promise of former bodies and thus given a lively presage of what the undivided regular profession hereafter will be able to accomplish. The scheme of union eventually evolved is of itself an excellent proof of the administrative ability of medical men and is also an earnest for future progress in the organization of the profession. Many, many difficulties had to be met, many delicate questions faced, and problems solved. It has all been well done and the Joint Committee of the two organizations deserve the congratulations as well as the thanks of their professional brethren.

President Hadley's general address at the evening session of the first day's meeting was one of the most important contributions to a true theory of professional education that has ever been voiced before a medical audience at least. His subject was "Conflicting Claims of General and Professional Education." He insisted especially that while early devotion to a profession might make the student a better and an earlier money getter, it did not make so good a man of him. As far as his own personal satisfaction in life and the possibility of making him capable of breadth of view, wide sympathy with his fellow-man and a useful citizen of the commonwealth the narrower professional education was a mistake. The sooner a man's mind turned to his life work the better, but the longer he delayed the narrowing influence of an active professional career also the better.

President Hadley did not hesitate to say that the same premature professionalism has impaired the usefulness of the legal professions. There are more lawyers with large incomes, but fewer Websters and Calhouns than in the old days when the commercial spirit was not so dominant. The motive to make money is not unworthy in itself and when prompted by the

desire to support the family in proper dignity it is even noble, but when it becomes the motive to the exclusion of all others life is not worth while and man's place in the community is lowered to an unworthy degree. President Hadley does not favor the shortening of the college course so as to enable students to begin their work in professional schools sooner, but believes in having many studies undertaken with broader view in the college department count in the medical curriculum. For him anatomy or chemistry studied in the non-professional course is sure to be of more true educational influence than if studied after the specialistic methods of the medical school.

Dr. Algernon T. Bristow's address as retiring President was one of the best of the Presidents' addresses at any Society meeting in recent years. Its subject was "The Status of the Medical Expert." It was an eminently illuminating exposition of one of the saddest phases of modern medicine and at least the abstract which we present should be read by every medical man with the interests of the profession at heart. The Scientific business of the session generally was of very high order. The symposia on Diabetes, on Abdominal Pain and on Nephritis shared in by some of the best special authorities on the various subjects were full of practical interest and suggestions. They contained very little that was mere repetition of previous knowledge and still less of mere conventional information. The sessions were all well attended, even to overflow in the afternoons and evenings, and the Medical Society just before it turns over the new leaf that makes it really the representative of all the regular profession has given an excellent proof of the vitality it retained during all the years of individual existence.

DENTISTS AND PHYSICIANS.

Now that the conditions of the practice of medicine have improved to such an extent as to eliminate many of the evils of a former time it is important also that the practice of dentistry on the highest ethical lines, as a significant department of medicine, should be encouraged by the physician. In recent years the possibilities of even serious gastro-intestinal disturbance as a consequence of bad teeth have come to be generally accepted by conservative medical men. It is not alone that the teeth are an important digestive organ, quite as indispensable for the preparation of food as the stomach itself, but also the presence of carious teeth furnishes a very favorable culture medium in the mouth on which large numbers of bacteria are constantly multiplying and carried down into the lower digestive tract where they may work very serious harm. Whether the contention that this may even cause pernicious anemia be true or not there is no doubt of the possibilities for evil it involves.

All of us have had the experience of discovering that an obstinate case of indigestion, which resisted all ordinary medical treatment, yielded promptly when the patient was provided once more with a proper mastication apparatus and the food was duly prepared for the stomach's action. On the other hand, very few physicians have failed to have the unfortunate experience, after advising patients to consult a dentist, to find in a very short time that the work done within the mouth was not of a kind to give any fair promise of lasting benefit. Dentists either incapable or so hurried that they do not do justice to their patients often make matters worse after slight temporary improvement, to the utter discouragement of the dyspeptic patient, already sufficiently downcast as a result of his stomachic condition.

At the present time, in the large cities of this country particularly, advertising dentists who offer bargains in dentistry are so common and their notices so prominent that many people, if advised to go to a dentist simply without any further directions in the matter, will be almost sure to consult one of these advertisers. As might be expected under the circumstances, the work is botched, for advertising is costly; inexperienced assistants are employed; the operators being very often young and comparatively untried dentists—recent graduates who have not as yet had opportunities that enabled them to judge how teeth should be treated. The consequence is that not infrequently too large fillings are inserted after the destruction of portions of the teeth that need not have been sacrificed, and these fillings are inserted with such lack of skill that within a few months, at most a year or two, the teeth, in worse condition than ever, require to be cared for once more.

No physician at the present time should ever treat a patient complaining of symptoms of indigestion without a thorough examination of the teeth. If the teeth present are insufficient for proper mastication, or if there are carious teeth the patient should at once be recommended to consult a good dentist. It is not, however, sufficient

simply to suggest any dentist, but the patient should be given a good idea of the risk involved in consulting anyone but some member of the dental profession who is thoroughly responsible and whose skill can be relied upon to do what is best for the patient. There is no doubt that physicians can in this way contribute in an important degree to the uplifting of the sister profession of dentistry and enable it to escape some of the demoralization incident to the large number of bargain-counter dentists in the field.

ECHOES AND NEWS.

NEW YORK.

German Hospital Appointments.—Drs. Richard Weil and Otto Hensel have been appointed Pathologists to the German Hospital.

Alumni Association of the College of Physicians and Surgeons, New York.—A smoking concert, under the auspices of the Alumni Association, will be held at Sherry's, Fifth avenue and Forty-fourth street, Monday, February 8, 1904, at 8:30 P.M. Vaudeville entertainment and supper. Tickets may be obtained by sending $2 to E. T. Boag, Registrar, 437 West Fifty-ninth street, New York City, on or before Friday, February 5.

Home for Convalescent Children Given to Orthopedic.—It was announced last Monday at the annual meeting of the New York Orthopedic Dispensary and Hospital, No. 126 East Fifty-ninth street, that Miss Emily A. Watson had given $100,000 to the institution, for the establishment of a branch at White Plains. Miss Watson has also agreed to endow the new home with a fund of $250,000, which makes the total amount of her gift $350,000. She is a member of the hospital Board of Supervisors. The new home will be called the Country Branch and Industrial School. Here convalescent crippled children will be sent, and they will receive an industrial education, besides medical care. Several years ago Miss Watson gave $60,000 to the hospital.

Cornell University Medical College.—The Faculty of the Cornell University Medical College has inaugurated a new scheme in the lines of instruction given by the subordinate professors and their assistants. There are a number of these men who are conducting more or less specialized lines of research in which they excel, and it has seemed desirable to give the students the benefit of the instruction these men are capable of giving and at the same time present a summary as well as detailed knowledge of all the advances made in the different branches in which these professors are experts. In the Department of General Surgery, Prof. Stimson has requested Prof. Kammerer to give the students the benefit of his knowledge upon intestinal obstruction, and Prof. A. B. Johnson upon the surgical disorders of the breast. In General Medicine, Prof. Thompson has asked Dr. Connor to do the same for the subject of the ductless glands, and Dr. Camac will take up the practical aspects of infection and immunity. In General Pathology, Prof. Ewing will inaugurate the work by lecturing himself upon the scientific mechanism of immunity. Dr. Schlapp will follow with a few lectures upon localization in the central nervous system, and Dr. Schultze will end the course with a few lectures upon cerebral hemorrhage, for which he has perhaps the best collection of gross specimens in the country. These lectures will be delivered before the fourth and third year classes of the college. Some of the subjects, however, are of such general interest that invitations will be sent to all members of the Faculty and practitioners who may be interested.

Columbia University.—At a meeting of the trustees of Columbia University, held on January 4, 1904, it was voted to fix the annual fee for tuition in the Schools of Applied Science and in the College of Physicians and Surgeons at $250 from and after July 1, 1904. The annual tuition fee in these schools is at present $200. Since the present fee was fixed the equipment of Columbia University in these departments has been greatly increased, and the number of instructors multiplied. The cost of giving the instruction in applied science and in medicine has steadily grown year by year, and is now not less than twice the amount received from fees for tuition. The tuition fee at the Massachusetts Institute of Technology is already $250, and the fee for New York students who attend the Stevens Institute of Technology at Hoboken is $225. The per capita cost of instruction at Columbia is believed to be greater than that at either of the institutions mentioned. Because of the recent changes in the curriculum at the College of Physicians and Surgeons and because of the new requirements for admission, the per capita cost of instruction there has been increased greatly also. Because of the ample provision made at Columbia University for scholarships which meet the cost of tuition, and for assisting students to pay their own way while taking a university course, it is believed that no deserving student will be deprived of the privileges which Columbia University offers because of the tuition fee.

Charities Report to the Commission in Lunacy.—The eleventh annual report of the State Charities Aid Association to the State Commission in Lunacy has just been issued. Regret is expressed at the failure of the legislature to take favorable action on the bill providing for the establishment of a reception hospital for the insane in this city. The establishment of such a psychopathic hospital has been urged for years by the State Charities Aid Association. Gov. Odell, in his annual message to last year's legislature, expressed himself in favor of the recommendations made, and the legislature for years has committed itself as favoring such a measure, but has done nothing to provide the necessary funds, $300,000, called for in the bill. The report contains the recommendation that an earnest effort be made during the present year to carry the plans for the reception hospital into effect. There should be one such hospital in Manhattan to accommodate about 200 patients, and another in Brooklyn to accommodate about half that number. It is further recommended that these hospitals be located in that portion of each borough, easy of access, and be organized and equipped like other hospitals for the treatment of mental diseases. A measure that meets with the unqualified commendation of the association is the creation by the legislature of the office of Medical Inspector to the State Commission in Lunacy. This State, it is declared, has a smaller representation of the medical profession on its commission than any other, despite the well-known fact that where medical men form a large part of the State commission "there is less danger that the scientific care of the patients will be subordinated to business interests than where the proportion of medical men is reduced to a minimum."

Work of the Crippled Childrens' Hospital at Tarrytown.—The work accomplished by the New York State Hospital for the Care of Crippled and Deformed Children at Tarrytown, N. Y., is set forth in the third annual report of the institution. Dr. Newton M. Shaffer, Surgeon in Chief, makes an earnest appeal for the names and addresses of children who are fit subjects for the institution's care, the age limit being between four and sixteen years, while hopeless cases and children whose guardians are able to pay for treatment are barred. Although the hospital has accommodations for only 25 patients, 52 have been received during the thirty-four months in which it has been in existence. Of these 33 suffered from tuberculous diseases of the joints. There were 27 discharged, of whom 19 were cured, while all were more or less improved. There have been 18 surgical operations on 9 patients, with marked benefit in every case. The average time of treatment of those discharged has been fifteen months and eighteen days. Some of the children operated upon by Dr. Lorenz at the Cornell Medical College Clinic in this city in December, 1902, were cared for during recovery.

City Hospitals Overcrowded.—Bellevue and all its allied institutions are crowded to their full capacity, and to meet the overflow many patients now have to be accommodated on mattresses placed on the floors. The meeting of the trustees, which was informal, was productive of no definite action, but Superintendent Rickard said that on Wednesday, when another meeting of the board will be held, a resolution will be adopted for presentation to Mayor McClellan, asking him to do what he can toward enlarging the institution's facilities.

A census of the patients at Bellevue last week showed that while there are 837 beds there were then 904 patients, the surplus being placed on the floors. Two hours later fifty more patients had been admitted, so that at 10 o'clock 120 patients were lying on improvised beds on the floor. At the Harlem Hospital, which has 44 beds, there were 45 patients. At the Fordham Hospital there were 43 beds and 42 patients. At the Gouverneur Hospital there were 82 beds for 84 patients. The overcrowding was still more emphasized by the report from the Blackwell's Island institutions. At the City Hospital, which has 629 beds, 48 patients were lying on the floor. In the Metropolitan Hospital with with 925 beds, there were 965 patients, 40 being forced to lie on the floor. An unusually large number of cases of pneumonia, amounting almost to an epidemic, has been the reason, according to Superintendent Rickard, for much of the present overcrowding. There are 200 pneumonia cases at Bellevue now. Of the fourteen deaths at the institution yesterday, six were from that disease.

Lecture by Doctor Trudeau.—On January 21, Dr. E. L. Trudeau, at the invitation of Professor James, lectured before the third and fourth year classes at the College of Physicians and Surgeons on "The Relation of Immunity to Pulmonary Tuberculosis." In introducing Dr. Trudeau, Prof. James spoke of him as a representative alumnus of the college, whose life had been given up to the study and prevention of a single disease. After a brief review of the various kinds of immunity, the speaker referred to the more recent work of Behring and to his so-called "Isopathic" immunity obtained in variola and anthrax. This protects longer than any other form and seems to come nearest to nature's method. It seemed a hopeless task to try to produce an artificial immunity in tuberculosis, when nature herself does not do it, but he was led to believe in the possibility from the fact that in autopsies healed foci are seen that remained healed, even though the patients were daily exposed to a reinfection. This was not an absolute immunity, but the resistance of the individual was increased to a point where he gained a victory over the incursion of the death-dealing germs. Referrng to the first crude and laborious attempt in starting a sanitarium at Saranac Lake, there were at least two things in the world that were never recorded, viz., resistance to temptation and the glory of honest but unsuccessful work. Everybody present knew how often he had failed and how it sometimes tempted him to become discouraged. In 1883 he began the experiment of inoculating rabbits with bacilli from birds. Rabbits were protected by the use of attenuated bacilli, and he is now able to get a vaccine eleven years old from bacilli no longer virulent, though having all the morphological appearances of the original. Seven years' work has failed to procure an antitoxin for tuberculosis, but the tuberculin treatment in his hands has been of some benefit, although it should be given only in selected cases, never to pyretic cases. Sanitarium treatment represents what we know; laboratory experiment what we hope for. It was necessary to prove that infection in a sanitarium is no more prevalent than anywhere, in fact, it is less so from actual experiment. The cottage plan of segregation with plenty of sunlight and air had helped to solve the problem Conditions necessary for successful treatment are: climate, rest, fresh air, food, and discipline. One great advantage of sanitarium treatment is that patients are not allowed to overexercise. If a man has any fever or spits blood he is kept quiet, and it is found that exercise is not necessary for him to keep up his appetite. When relapses occur from any cause patients are put to bed and kept in the open air; but everyone cannot sleep out-of-doors because some patients contract neuralgias, sleep badly and cannot get used to it. About 51 per cent. of all cases, however, do well under this method, even with the thermometer at 42° below zero. A series of beautiful lantern slides illustrating the grounds, buildings and general life at the institution completed a very interesting and profitable hour.

Mt. Sinai Hospital's Year.—It was announced by President Isaac Wallach, at the annual meeting of the Directors of Mount Sinai Hospital, held at 149 East Sixty-seventh street yesterday, that the hospital would probably move to its new buildings, Fifth and Madison avenues and One Hundred and First streets, about March 15 or 16. The entire subscriptions to the building fund aggregated $1,435,568.76 on Dec. 1, 1903, $152,139.64 of which was received last year. The expenses of the hospital for the last year amounted to $151,838.22, and the applicants for admission aggregated 6,496, of whom 3,540 were treated in the hospital. This makes a grand total of 76,891 patients admitted to Mount Sinai Hospital since its founding. Taking the patients treated in the hospital, the dispensary and outdoor department, 36,366 patients were treated last year, and the death rate was 10.34 per cent.

Manhattan Dermatological Society.—Regular monthly meeting was held January 8, 1904, at the residence of Dr. I. P. Oberndorfer; Dr. Oberndorfer presiding. The following cases were presented. Dr. J. Sobel presented a female, twenty years old, with an eruption of varying-sized patches and papules of a marked scaly nature; at first observed on flexor surfaces of arms, then on chest, back and extensor

surfaces of upper and lower limbs; the hair line on forehead is likewise scaly. Dr. Sobel was in doubt whether to call it a true psoriasis, a seborrhoid eczema, or an eczema seborrhoism psoriasiformis. Dr. Pisko thought he recognized some typical papules of psoriasis on knees and elbows; the atypical aspect on lower arms he considered due to effects of treatment. Dr. Oberndorfer also observed lesions of psoriasis; the thick crusting on the arms was unlike eczema seborrhoicum; the latter and psoriasis he recognizes as two distinct affections.

Dr. Gottheil placed this case on the boundary line of psoriasis and eczema seborrhoicum. Dr Sobel favored the diagnosis of eczema seborrhoicum, owing to the greasy condition of the scales; the involvement along the hair line of the forehead and the general oily condition of the skin.

Dr. W. S. Gottheil presented the following cases: (1) A boy of ten years of age, showing small, acuminated lesions, with central depression, from which sebaceous-like material could be expressed; situated on the dorsum of both hands, and present about eight years; some lesions disappear spontaneously. He termed it acne corneus. Dr. L. Weiss coincides with this diagnosis and stated that the condition was extremely rare. (2) A typical case of eczema marginatum; of interest was the extensive involvement; almost the entire back, chest and abdomen were involved. (3) A case of epithelioma (upper cheek near eye) in a male, showing excellent results from the use of Marsden's paste. (4) A typical case of lichen planus; the hands and feet well show the glistening, silvery appearance; lower arms and lower legs studded with innumerable papules, and the chest, abdomen and back showing isolated lesions; the mucous membranes of buccal cavity likewise involved. He gives large doses of a 1 per cent. sol. sodium arseniate, 40 to 45 drops, and patients stands the treatment well; no pigmentation following was observed. Dr. Pisko is using a solution of arsenious acid called atoxl also with excellent results. (5) A case of ulcerating lesions involving mucous membranes of the entire buccal cavity, including tongue, tonsils and epiglottis. The patient, a woman of thirty-five years, is asthmatic and poorly nourished, suggestive of tuberculosis, although the lungs show nothing positive. With antisyphilitic treatment conditions became worse; patient now on local soothing applications, with little or no improvement within the past six weeks. A laryngologist pronounced the condition probably pemphigus. Drs. Pisko and Sobel both entertained the latter diagnosis; mouth pemphigus alone is possible without any skin lesions. Dr. Oberndorfer regards it a severe stomatitis; its chronicity could be explained by the poorly nourished state of the patient, who might be tuberculous. Dr. Weiss asked: Is this a case of foot and mouth disease? In tuberculosis of these parts he expected to find the rim of the epiglottis involved. Dr. Abrahams suggested a chronic herpes.

Dr. A. Bleiman showed a man of fifty-four years with superficial ulceration involving roof of mouth adjacent gum, soft palate and neighboring left tonsil; present about one year and about stationary; he sought no advice until three weeks ago. Patient gave an indefinite history of lues contracted thirty-five years ago, but in this long interval never showed any of its manifestations. Condition gives rise to no inconvenience. The right and left side of neck each show an immense enlarged gland. Tentatively placed on KI, patient begins to show slight improvement. Regardless of this improvement the lesion strongly suggests malignancy. Drs. Weiss, Gottheil and Oberndorfer considered syphilis, tuberculosis and cancer. They, however, regarded it as malignant, and could exclude the other two. Dr. Geyser suggested X-ray with a special tube for mouth cases. Dr. Sobel thinks it is malignant, but would suggest very large doses of KI and note the result. Dr. Pisko thought it might be specific, and related a case of a man, eighty-nine years old, whose syphilis contracted at the age of twenty-one, never showed any lesions until one year ago, when subsequent events proved the lesion to be a gumma. Drs. Cocks, Abrahams and Ochs called it malignant.

Dr. I. P. Oberndorfer showed a boy of five years. The present eruption began at the age of two years; lesions consist of numerous, varying-sized blots upon a deeply reddened and somewhat infiltrated skin; some scratching and excoriations were also observed. Mucous membranes not involved; the entire body is involved, including face and scalp. The boy's bodily nutrition has not suffered, and aside from subjective symptoms is in good physical condition. Presented as a case of pemphigus vulgaris. Dr. L. Weiss stated that the physical well-being of the child favored diagnosis of pemphigus vulgaris; if pemphigus foliaceus, the prognosis was extremely bad; he saw good results with the permanent bath. Dr. Gottheil also believes the prognosis to be good in this case; if pemphigus malignans, would expect to see greater constitutional disturbance. Dr. Abrahams said pemphigus foliaceus tends to progression and the prognosis is extremely bad. The absence of excoriations and mouth lesions favored diagnosis of pemphigus. Dr. Pisko described a condition known as urticaria bullosum; it begins as an urticaria; vesicles and blebs develop and finally shows a picture resembling pemphigus simplex.

Dr. R. Abrahams showed a woman of thirty-five years, with rounded semi-cartilaginous tumors along the back of both arms (elbow region) and along the phalanges; of about four years' duration; painless and about the size of a large cherry; non-adherent and movable; no history of rheumatism or gout; no apparent connection with the joints. He termed it multiple fibroma. A second case, shown by Dr. Abrahams, with the following history: A male of thirty-five years noticed a small pimple on side of nose about four months ago; this he stated was treated by injection and cauterization; following which the present condition confronts us; a large oval, deeply excavated ulceration with raised margins and sharply defined border. The patient placed on KI; healing is slow, but improvement nevertheless marked since beginning of treatment. Drs. Pisko, Gottheil, Cocks and Oberndorfer called it an ulcerating gumma. Dr. Weiss said infection might have been accidental; its appearance suggested syphilis. Dr. Ochs thought it resembled rodent ulcer.

Dr. B. F. Ochs presented three cases: (1) A male with three distinct lesions—*a*, multiple lipoma on arms and abdomen; *b*, alopecia areata (scalp), and *c*, ringworm of the beard. (2) Male; twenty-seven days after suspicious coitus noticed an ulcer on prepuce; painful and enlarged inguinal glands now present; skin clear. Owing to long period of incubation in doubt whether to call it true or simple chancre. The ulcer was considered a chancroid; Dr. Sobel contending that other forms of irritation could produce such an ulcer. (3) Male; presents five or six distinctly raised papillomatous-like lesions along borders of upper and lower lips; present about eight months. Dr. Sobel thought the original lesion might have been a mole and present condition due to irri-

tation. Dr. Weiss called it papilloma, as did Drs. Oberndorfer, Gottheil and Pisko. Dr. Abraham considered it specific; he said, if seen on genitals, would surely call it specific.

PHILADELPHIA.

Medical Jurisprudence Society.—At the annual meeting of this society held January 18, Judge William N. Ashman was elected President; Dr. Henry Leffmann and Paschal H. Coggins were re-elected Secretary and Treasurer, respectively.

Officers of County Medical Society.—At the annual election held on January 20, the following were elected officers of the Philadelphia County Medical Society: President, Dr. Roland G. Curtin; First Vice-President, Dr. Franklin Stahl; Second Vice-President, Dr. Chas. P. Noble; Secretary, Dr. William S. Wray; Assistant Secretary, Dr. R. H. Skillern; Treasurer, Dr. Collier L. Bower; Censor, Dr. H. St. Clair Ash; District Censor, Dr. Albert M. Eaton.

Smallpox Increasing.—For the week ending January 22 there were reported 106 new cases of smallpox, the largest number in any one week for more than three years. Deaths from this increase were 11 less than during the previous week. Deaths from all causes numbered 618, this being 118 less than the week before when the death rate was unusually high.

New Sanatorium for Consumptives.—It is stated that the erection of a sanatorium for the treatment of consumptives will early in the spring be begun at Summit Hill, Pa. A number of Carbon county capitalists are interested in the project and patients are to be treated at very low rates. Climatic conditions are considered excellent. The institution will be conducted on lines similar to that at White Haven.

Butler Relief Corps Returns.—The four physicians and the remainder of the 25 nurses who were at Butler during the height of the typhoid epidemic, returned to this city January 20. The Hospital of Brotherly Love, so named by the inhabitants of Butler, maintained by them there was closed the day before they left, the remaining patients being convalescent and sent to other hospitals. The record made in the hospital was very gratifying, only two deaths occurring in that institution. The gratitude of the citizens of Butler was voiced by Judge Galbraith, who, speaking for the Relief Committee, said in part: "I have said on several occasions that Philadelphia has earned anew the right to be called 'the City of Brotherly Love,' because, when our people were in the throes of an epidemic, many of them suffering and in need of help, then it was that Philadelphia did one of the noblest and grandest things in the way of help for human kind that I have ever known; and I am sure that what they have done for Butler in its present condition, coming here as they did, offering their help, and the way in which they helped, has endeared Philadelphia to Butler for all time to come. This epidemic will go down, I have no doubt, as an epoch in the history of Butler County, and the generations to come will turn back to the year 1903 as 'the year of the epidemic,' and I think that in addition to that historical fact will go down through our annals what Philadelphia has done for Butler."

Milk Supply of Philadelphia.—At a recent meeting of the Keystone Veterinary Medical Association, Dr. Leonard Pearson, State Veterinarian, said that though the great bulk of milk being shipped into Philadelphia was wholesome enough there is still enough contaminated milk sold daily to destroy many lives. The reason given was that the dealer seldom visits the farm where the milk he distributes is produced and at the same time in his dealings forces the farmer down to the last cent. Dr. Pearson said further: "One would naturally expect that the milk purchased by benevolent institutions like our hospitals would have been specially scrutinized, but when an inquiry was started it was found that only three of our hospitals paid any attention to the purity of the milk they fed their patients. The others not only purchased the ordinary market milk, but the determining question as to who should be selected to supply it was the question of price. The dealers assumed that milk good enough for a hospital was good enough for any one. Through the efforts of Dr. Martin and the Health Bureau all the hospitals are now using pure milk." Other speakers stated that more than three thousand quarts of certified milk, at an advance of two cents per quart, are being consumed here daily and the demand is increasing. The position of the dealer in regard to certified milk was stated by Dr. George Abbott. He took the ground that, as good milk is more expensive of production than bad milk, the consumer will get good milk when he expresses a willingness to pay more than he now pays.

Dismissal of Medical Student Upheld by Court.—The efforts of Mrs. Elizabeth O. White to compel the Trustees and Dean of the Woman's Medical College to allow her to resume her studies at that institution have for the present failed. It is stated that an appeal will be taken to the Supreme Court. Mrs. White passed the examinations of the first year satisfactorily, but on her return in the fall was refused admission as a student. No specific reason for this was given by the Dean, only the general statement being made that because of information received the refusal was best for the institution.

CHICAGO.

To Control the Milk Supply.—It is stated that capitalists are planning to control the milk supply of Chicago. According to reports, "the Chicago Dairy Company was organized in Maine, with a capital of $4,000,000. The intention of the promoters is not to raise prices, but to earn the gratitude of the public by prompt service and to keep milk free from any contamination."

Inspection of Hospitals.—Another and more rigid inspection of private hospitals, with special reference to their precautions against fire, was begun during the week. The last previous inspection, in the Spring of 1902, was made by the Building Department alone. The one now being made is, under the joint direction of that department and the Department of Health, a Building Inspector and a Medical Inspector working together in each investigation, and making joint reports to each department. In this way it is hoped to secure better results in the matter of prompt remedy of defects discovered.

Pneumonia.—A comparison of the New York with the Chicago figures of deaths from pneumonia and consumption up to Jan. 2, the date of the last New York report received, shows a close agreement as to pneumonia, but a wide difference as to consumption. The pneumonia deaths formed 18.6 per cent. of the total mortality in Chicago, and 18.7 per cent. in New York. On the other hand, while the consumption deaths were 12.1 per cent. of the total deaths in New York, they were only 0.3 per cent. in Chicago. Chicago's deaths from consumption were 30 per cent. less than New York's.

To Muzzle Dogs.—On January 18, at its regular meeting, the Chicago City Council passed an ordinance providing that dogs must be muzzled all the year round unless led by a chain. The fine imposed for the violation of this ordinance is to be not less than $2, nor more than $10. It will be remembered that the City Council was prompted to take such a drastic measure

by a paper read by Dr. Arthur Dean Bevan at a meeting of the Chicago Medical Society, in which he depicted the horrors of hydrophobia, and subsequently resolutions were adopted by the Society asking for the passage of such an ordinance.

CANADA.

Personal.—Professor W. D. Halliburton, F.R.S., Professor of Physiology in King's College, London, England, delivered a lecture on the Degeneration and Regeneration of Nerves, with lantern slide illustrations, before the Medical Faculty and students of Toronto University on January 22.

Appointments.—Dr. J. T. Moher, Assistant Superintendent of the Institution for the Feeble-minded at Orillia, Ont., has been transferred to the position of Medical Superintendent of the Brockville Insane Asylum, to succeed the late Dr. J. B. Murphy. Dr. Peter H. Bryce, Secretary of the Ontario Board of Health, has been appointed Inspector of Immigration for the Interior by the Dominion Government. He will likely be succeeded by Dr. C. A. Hodgetts who has been discharging for some time the duties of Provincial Health Inspector. Dr. Bryce in his new sphere will also have charge of supervising a new system of medical inspection which it is proposed to inaugurate among the Indian tribes of the Northwest Territories.

Typhoid Fever in Montreal and Suburbs.—The epidemic of typhoid fever which has been raging in Montreal, but particularly in the suburbs of Westmount, St. Louis and St. Henri, is now said to be well in hand. In all there have been over 600 cases, and the cause has been put down to the quality of water furnished to these municipalities. At the present time there are between 120 and 130 cases in the different hospitals of Montreal, and no new cases can be taken in the General and Royal Victoria Hospitals. The Provincial Board of Health of Quebec has had to step in and take a hand in managing the epidemic and have issued a special circular to the physicians of Montreal and suburbs asking for their co-operation in checking the epidemic. During the week ending Jan. 16, there were nine deaths reported from the disease. As only a few cases have developed within the past few days, it is considered that at last it is well in hand.

Western General Hospital, Montreal.—The annual meeting of the Board of Governors of the above institution was held last week, when it was reported that the number of patients treated in the institution in 1903 was larger than for any previous year, and that after deducting the cases which terminated fatally within forty-eight hours of their admission, the death rate was only three per cent. The report also stated that each day the necessity for a new hospital building was becoming more and more marked. Those treated in the hospital during 1903 numbered 600, which was an increase of eleven over 1902. In the outdoor department the number treated was 7,560, or an increase of 990 over the previous year. The average number of days' treatment in the hospital was 18.3, and the total of days' stay was 11,176. Dr. G. H. Matthewson was elected secretary and Drs. F. W. Campbell and F. R. England medical representatives on the Board of Governors.

Royal Victoria Hospital, Montreal—Annual Meeting.—The following appointments were made to the medical staff: Assistant surgeons, Drs. E. W. Archibald and C. B. Kenan; assistant laryngologist and rhinologist, Dr. W. H. Jamieson; associates in medicine, Drs. H. B. Cushing, F. M. Fry and John McCrae; director of the clinical laboratory, Dr. A. A. Bruyere; clinical assistants in neurology, Drs. A. A. Robertson and Malcolm Mackay; clinical assistant in medicine, Dr. Phillip Burnett; clinical assistant in ophthalmology and otology, Dr. F. W. Harvey; second assistant pathologist and registrar, Dr. John McCrae; assistants in bacteriology, Drs. H. B. Yates and J. A. Williams; medical registrar, Dr. H. B. Cushing.

GENERAL.

Tuberculosis Exposition at Baltimore.—The Tuberculosis Exposition at McCoy Hall, which is given under the combined auspices of the Tuberculosis Commission of Maryland, the State Board of Health and the Maryland Public Health Association, was formally opened last Tuesday, to continue throughout the week. It is "an objective presentation to the people of Maryland of the history, distribution, varieties, cause, prevention and cure of tuberculosis," and the careful and elaborate preparations made indicate that, wide as this scope seems to be, the purpose will be amply achieved. The exposition is the most important step yet taken in the crusade against the "white death" in this State, and, being the first of its kind ever held in this country, is attracting so much attention from medical men and scientists in all parts of the country and has received so many exhibits from far and near that it takes on a really national importance. A fuller review of its program will be given next week.

Typhoid at Leadville, Colorado.—A serious epidemic of typhoid fever prevails at Leadville, according to Claude E. Copper, secretary of the board of health. Mr. Copper says there were 500 cases of the disease in Leadville on Jan. 21, and expresses the belief that it will spread. He says the situation is serious, not only because of the rapid spread of the disease in Leadville, but from the fact that there is danger of the Arkansas River becoming contaminated, which would jeopardize the health of thousands of persons along its banks.

Inventor of Iris Diaphragm.—Mr. John Henry Brown, the inventor of the now widely used iris diaphragm, died on December 19, at Hove, England, aged sixty-seven years. He was a dentist, and never having patented his invention, reaped no pecuniary reward from it. In the early seventies he took his home-made model to Smith & Beck, the well-known opticians in Cornhill. The model, although roughly constructed, differed in no essential particulars from the diaphragm at present on the market. Mr. Brown was a fellow of the Royal Astronomical Society.

A Unique Departure.—Year-books are plenty, and in the well-known English weeklies a retrospect of progress is to be found at the close of each year. The *Interstate Medical Journal* has this year published an extra number, a "Special Annual Medical Progress Number," which contains a summary of the year's work, which has been very wonderfully compressed and makes a valuable reference number. We wish the *Interstate* success in its venture.

Japan's Medical Service.—The *British Medical Journal* says the Japanese military medical arrangements are so extremely up-to-date as to be scientifically comparable with those of any nation, while in point of generosity of the provision of medical officers, elasticity and adaptableness to varying conditions, the difference is, perhaps, in favor of Japan. Thus, while base hospitals, field hospitals, dressing stations of three types, bearer companies, and hospital ships all find their place, each division of the army has a medical reserve, which is mobilized simultaneously with it, and serves in the base or reserve hospitals. The medical department also has its own independent transport, and every infantry regiment, cavalry, artillery, engineer, and general transport battalion has a medical staff attached to it of a very complete kind. Besides all these

standing arrangements, the regulations provide for an automatic addition to the personnel of the hospitals in accordance with the number of patients present, without reference to headquarters. Moreover, so long as a military medical officer remains in chief command additions may be made from the civilian population; everything, too, is done to facilitate the co-operation of the Japanese Red Cross Society.

OBITUARY.

Dr. Edward B. Dana, Jr., died at his home in Main street, Metuchen, N. J., last Thursday night, of pneumonia resulting from overwork and exposure in attending to a very large practice. He was about forty-three years of age, and was president of the Board of Health and of the Board of Education.

Dr. Virgil M. D. Marcy died suddenly at his home, in Cape May, N. J., Jan. 21, aged eighty-one years. He was born in Cape May, Jan. 5, 1823, was graduated from Yale in 1844, and two years later from the medical department of the University of Maryland. He was on the first college boat crew that ever rowed in this country. He was a prominent Presbyterian and practised medicine in Cape May from the time of his graduation. He was prominent in Masonic circles.

Dr. Edmund Andrews.—On Jan. 17, Dr. Edmund Andrews underwent an operation for stone in the bladder, the operation having been done by his sons, Drs. E. Wyllys Andrews and Frank T. Andrews. The distinguished patient bore the operation well, and had practically recovered. About noon of Jan. 22 he was seized with cardiac paralysis, and soon expired. Five years ago the first symptoms of valvular trouble of the heart were discovered. For forty-eight years Dr. Andrews was engaged in the practice of surgery in Chicago, retiring two or three years ago. He was born in Putney, Vt., April 22, 1824. He removed with his parents to Detroit, Mich., in 1840, and was graduated from the Literary Department of the University of Michigan in 1849. Three years later he completed a course in medicine at the University and came to Chicago. In 1857 Dr. Andrews occupied a professorship in Rush Medical College and taught there for three years. At that time only two years' study were required for graduation, and, advocating a longer course, Dr. Andrews, with five other physicians, established Lind University. The University was the first to require a four-year course. In 1860 the college was absorbed by the Northwestern University, and Dr. Andrews was appointed Professor of Surgery. At the beginning of the Civil War Dr. Andrews was appointed Surgeon-in-Chief of Camp Douglas, and later was made surgeon of the First Regiment of Light Artillery. With the regiment he saw service in Tennessee and Mississippi. In 1854 Dr. Andrews founded the Chicago Academy of Sciences, and for many years was one of its most active supporters.

Etiology of Exfoliative Endometritis.—A very probable explanation of this condition is furnished by S. Gottschalk (Dent. med. Woch., Vol. 29, No. 48). In the case which he describes there were numerous thrombi in the veins of the uterine mucosa. The mucous membrane had become detached by a dissecting effusion of blood, similar to that which takes place in a premature detachment of the placenta. He believes that these thrombi were due to stagnation of the blood from weak heart action. Microorganisms were not found. He suggests that the routine treatment of scraping the interior of the uterus would be of no avail.

CORRESPONDENCE.

OUR LONDON LETTER.

(From Our Special Correspondent.)

London, January 9, 1904.

NEW YEAR HONORS—STATISTICS OF THE MEDICAL PROFESSION—THE STATE REGISTRATION OF NURSES—MUNICIPALITIES AND THE SUPPORT OF HOSPITALS—A NEW DEPARTURE IN SCIENTIFIC "TRANSACTIONS"—THE CHAIR OF MEDICINE AT OXFORD.

There must have been woful disappointment in the crowd of more or less eminent members of the medical profession who were looking forward to New Year's Day for the issue of a list of "honors," in which they hoped to see their own names. Only a few decorations have been given, and these are confined to the Indian Services. Henceforth the "fount of honor," as the Sovereign is styled by the heralds, will play only once a year—on His Majesty's birthday. The official reason is that the two dates are too close to each other; the real one, I suspect, is that Edward VII. has been so lavish in his bestowal of honors that it began to look as if he would in a few years have had no adult male among his lieges left to decorate.

The *Medical Directory* for 1904, which has just been published, shows that the total number of medical practitioners on the British Register is 37,730, being an increase of 439 as compared with last year. London has 6,328 doctors; there are 16,553 in the English provinces and 1,207 in the Principality of Wales; Scotland rejoices in 3,696, while Ireland has 2,629. The naval, military and Indian Services have together 3,016 medical officers, and there are 4,292 holders of British diplomas practising in the colonies and in foreign countries. Here as elsewhere medico-political economists are becoming alarmed at the steadily increasing output of doctors from the schools. A cry for protection is making itself heard from the general practitioners on whom the stress of competition falls most heavily; they ask that a higher standard of preliminary education should be required and that admission to the profession should be made more difficult. Pressure is put on the British Medical Association, which is rapidly developing into a trade-union, naked and unashamed, to take up the cause of the down-trodden practitioner and bring about a medical millennium. The clamorers for protection fail to recognize that the Association has little or no political influence, and that it has not even authority to speak in the name of the medical profession as a whole. Nor do they perceive that the whole problem is an economic one, which can be solved only in accordance with the law of supply and demand. There are doctors and doctors. While there will always be a demand for competent practitioners, the public has no use for the incompetent. And it must be confessed that this fact lies at the root of the hospital out-patient difficulty of which so much is heard. Practitioners complain that patients who could pay them a small fee are attracted to hospitals where they are treated for nothing, and they blame the hospitals for conniving at this abuse of medical charity. A large proportion of the general practitioners in this country have never acquired more than the irreducible minimum of knowldege required to carry them safely through an examination presenting no insuperable difficulties to persons of average intelligence, and in a very few years much of what they learned for the purpose has gone, like Hans Breitmann's party "afay in de Ewigkeit." That there is a good deal of abuse of medical charity is undoubted. But the real reason which makes so

many people not overburdened with money prefer the hospital out-patient department to the general practitioner's surgery is, to speak plainly, that they have no confidence in the latter. For the doctor the first condition of professional success is to create a demand for his skill. Those who throw the blame of their failure on the abuse of hospitals, on underselling by their brethren, on the multitude of quacks, assume that they have a right to be protected by the State and receive the support of the public. With the French prisoner they put forward, as if it were a first principle of Nature, the plea *Faut vivre*, and like him, alas! they lay themselves open to the retort from the public, *Je n'en vois pas la nécessité.*

For many years there has been a movement here to secure the establishment of a register on which the names of properly trained nurses should be enrolled. Something of the kind has indeed been attempted, but only as a matter of private enterprise. The nursing world is split up into several factions which hate each other as bitterly as rival religious sects. Hence any reform suggested in one quarter was certain to meet with strenuous opposition in the other. Now, however, there seems to be a prospect of a State register being established. A measure providing for such registration is to be introduced in the forthcoming session of Parliament. The bill has been drafted by the Society for the State Registration of Nurses, and a number of influential members of the House of Commons have already promised their active support. It is proposed to appoint a Central Nursing Council that will be representative of the medical and nursing professions. The duties of this Council will be to protect the interests of nurses and also to afford a safeguard to the public against untrained or ill-trained nurses, of whom there are said to be hundreds in London at the present time. The Council will regulate and supervise the training of nurses, and the names of none will be admitted to the Register unless they have satisfied the proper authorities of their competence to discharge the duties which they undertake. Besides the names the Register will contain the qualifications and addresses of nurses, and the list will always be open to the inspection by the public. As an illustration of the evils against which the bill is directed it may be mentioned that a week seldom passes without the occurrence of a case in the Coroners' Courts which reveals proofs of incapacity in women calling themselves nurses and gross mistakes committed by them. Naturally they find their chief sphere of operation among the poorer classes, to whom they represent themselves as efficient substitutes for doctors. A nursing authority has recently declared that the mortality attributable to these quack nurses is enormous. The passing of the bill will do much to check practice by such unqualified women, and cannot fail to be a boon to the sick poor.

The municipalization of hospitals has never found favor with the governing bodies of those institutions or with the medical profession of this country. All our hospitals owe their foundation to the charity or enterprise of private persons, and each one jealously guards its independence. If they were to be supported out of the rates, they would of course be subject to the control of the local authorities which levy the rates. It is largely a matter of accident whether those bodies are enlightened promoters of the public welfare, or narrow-minded Jacks-in-office, who grudge every penny needed for safeguarding the public health, and who would certainly not be less obstructive in the matter of providing funds for the efficient maintenance of hospitals. Hitherto the belief has been universal that under the Public Health's Act, local authorities had no power to make contributions to the support of local hospitals out of the rates. Quite recently, however, the Local Government Board has expressed the opinion that it appears to be competent for such authorities to make contributions to the funds of established hospitals. This is a new departure which is hailed with satisfaction by some hospital administrators, while by others it is regarded as the first step to the dreaded municipalization, with the consequent popular control. In connection with this matter it may be mentioned that there is now before Parliament a bill providing for the relief of all hospitals from the burden of rates independently of municipal action. This would doubtless be a great benefit to the hospitals from the financial point of view. The bill will, however, meet with some opposition if the general practitioners, who look upon such a concession to hospitals as an additional handicap on themselves in their struggle with those institutions, are able by lobbying M.P.'s to muster a sufficient array of force against the proposal.

The last three or four International Medical Congresses have been object lessons in the confusion of tongues, and thoughtful observers are becoming convinced that unless a remedy can be found, that institution will have the fate of the Tower of Babel, and for the same reason. At the Congress held last year at Madrid, five, if not six, tongues were recognized as "official," the result being that the meetings gave the impression that the debaters had, like Holofernes and his brother pedants in *Love's Labor Lost*, been at a great feast of languages and stolen the scraps. The want of a universal language of science is making itself more and more severely felt, for to keep up with the flowing tide of medical progress nowadays a man must be able to read at least half a dozen languages. Artificial tongues, such as Esperanto, will never, I think, come into general use; they are as difficult to learn as French or Italian, and when learnt, one has only a *lingua franca* without a literature. National jealousies stand in the way of the general adoption of any living tongue as the recognized medium of scientific intercourse, but there is one dead language which might well serve the purpose, as it did till the beginning of last century. Latin is still used for lectures, theses, and discussions in Catholic theological seminaries, and educated German, Italian, French and Spanish priests can converse with each other without difficulty. If English priests are somewhat less fluent in the colloquial use of Latin, this is due to want of practice. If Latin were properly taught in schools, boys intended for the medical profession would on leaving be sufficiently practised in its use to be able to make it a vehicle for the conveyance of scientific ideas. A disquisition on the subject is outside my province; the remarks here made are merely intended to serve as an introduction to the mention of a fact which may be the first sign of an important revival. Mr. S. G. Shattock, one of our leading pathologists, the editor of the *Transactions of the Pathological Society*, in the last number recently issued has prefixed to the principal papers a summary of their contents in the language of ancient Rome. The Latin might perhaps make Quintilian gasp and stare, but it is clear and precise and serves the purpose for which it is intended quite admirably. Mr. Shattock seeks to disarm the criticism of classical pedants by pointing out that graces of style would be out of place in setting forth scientific facts (*In re scientiæ modo postulatur expositio accurata rerum et legum quibus gubernantur, sine litterarum floribus aut ornamentis*). The matter is of

course in the experimental stage; but he has at any rate succeeded in proving that the fresh facts and new truths of modern pathology can be expressed with perfect clearness and accuracy in Latin. The innovation has already received the approval of several prominent scientific workers in this country.

Mention was made in my last letter of Sir John Burdon Sanderson's resignation of the Chair of Medicine at Oxford. There seems to be a prospect of a somewhat unedifying fight over the choice of a successor. At Oxford itself it is felt that the vacancy offers a good opportunity of making the chair of greater utility to students and of greater credit to the University by expanding the scope of the incumbent's teaching. An Oxford professor cannot teach practical medicine efficiently for want of an adequate clinical field. He has, however, the largest facilities for teaching pathology and for enlarging the boundaries of the science. It is proposed therefore to transform the chair of medicine virtually into one of pathology; to incorporate in it an existing "readership" in that subject, and to make the present holder of the latter office, Dr. James Ritchie, Regius Professor. This proposal is being strongly resisted by a considerable body of Oxford graduates, headed by the President of the London College of Physicians, Sir William Selby Church. This party holds that the Regius Professor should be "a physician of great experience in clinical work and clinical teaching;" that he should be "a man of established reputation in medicine and one who could worthily uphold the dignity of the University in the estimation of the profession and the public;" and further, that he should be himself an Oxford man. Dr. Ritchie is only an Oxford man by adoption, having, like Burdon Sanderson, received his medical training and taken his degrees at Edinburgh. Oxford men are by way of looking upon themselves as the salt of the earth, and the chief objection to Dr. Ritchie is doubtless that he is not one of the elect. He is, however, a man who has already won great distinction as a pathologist, and he has the further recommendations of youth, energy and openness of mind. It is to be feared that the Oxford graduates look upon the Chair of Medicine in their ancient University as a place of dignified repose for a cultured gentleman who combines a moderate knowledge of physic with distinctions of a purely academic kind. If Oxford is not to continue to be a "lost medical school" that is just the kind of professor she does not want.

THE "SANDHOG" AND THE CONTRACTOR.

To the Editor of the MEDICAL NEWS:

DEAR SIR: I have received from my friend, Dr. Noyes, a copy of the issue of the MEDICAL NEWS of Jan. 16, and following his request, I write you in relation to an editorial which appeared in that issue entitled, "The Bends and the 'Sandhogs.'"

I do this without any reference whatsoever to the medical aspect of the case, but purely in respect to the engineering side in relation more particularly to tunnel work.

Our specifications for air-pressure work have invariably contained a number of clauses providing for the preservation and care of the health of employes.

In the construction of the Hudson River Tunnel, which work we have been under the necessity of carrying on for the owners, we have fully enforced all the conditions stipulated in these specifications and the result has been that we have had hardly any cases of injury due either to "bends" or paralysis and only one death, while I do not now remember that we have had any case of permanent paralysis, notwithstanding that we have been engaged on this work with high-air pressure for nearly twenty months continuous work by night and day. From the engineering aspect of this class of work the matters which can be definitely regulated, comprise (*a*) the medical regulations; (*b*) the length of service under pressure; (*c*) the period allowed for decompression and (*d*) the provisions as to the purity of the air in the tunnel.

In caisson work it is usual and desirable to specify also the limit of temperature in the working chamber, but this does not give any trouble in tunnel work on account of the enormous relative volume of the working chamber.

In order to keep the temperature at a moderate limit of say 80° F. maximum, it is often necessary in caisson work to cool the air at the receiver after leaving the compressor, artificially.

In the first instance in our own construction work we enforce the strictest medical examination of all persons working under pressure. This is carried out by our own physician and he selects very carefully and limits employes rigidly in respect of the age of the applicant, being very liberal with candidates who are under thirty, and exceedingly critical of candidates who are over forty years of age.

The examination in respect to the ears is done by the engineers in a practical manner—that is to say, any candidate for work presenting himself, is taken into a light pressure, say fifteen to twenty pounds per square inch, before being engaged for employment, and any who are "blocked" by the pressure are promptly rejected.

Following the acceptance of men by the medical officer, rules have been laid down as follows, for the guidance of employes in preserving their health:

Hudson Improvement Company
NOTICE TO EMPLOYES
Engaged in Work Under Air Pressure.

The following rules, governing personal safety and health, must be carefully observed:

1. Never enter lock with an empty stomach.
2. Use intoxicating liquors sparingly. Take warm coffee freely.
3. Always put on extra clothing while coming out. Pass out slowly.
4. Exercise as little as possible for at least one hour after coming out.
5. Get fully seven hours' sleep in each twenty-four.
6. See that the bowels move every day.
7. Never enter the lock if at all sick.
8. Report all cases of illness at the office *immediately*.

A. J. LOOMIS, M.D.,
Medical Officer.

These notices are posted in the dressing rooms and in various places about the works in plain sight of all employes.

In regard to the length of service, we consider this an exceedingly important, in fact, the most important item in the case. In the construction of the East River Gas Tunnel under the East River at Seventieth Street, N. Y., we worked at times with a pressure as high as 52 pounds above the atmosphere or 67 pounds absolute, and in this case employed the men for two 1½ hour shifts per day with no injurious results. On the Hudson River Tunnel, however, we have not needed to work as high a pressure, as this at any time, and our maximum pressure has not exceeded 45 pounds above atmosphere or 60 pounds absolute. This pressure, however, has been worked under continuously for quite long periods, and the bulk of the work has been car-

ried on between the pressures of 50 and 60 pounds absolute.

Under these conditions we have had no trouble whatever in working the men six hours per day. This has been done, however, by working three-hour shifts and relieving the gang at the end of three hours by the fresh gang and the first gang laying off three hours and then returning to work, so that each of four gangs work three hours and lay off three hours, and work again three hours, constituting in this way, the full twenty-four hours uninterrupted employment.

As we have reduced the depth of the tunnel and consequently reduced the necessary air pressure under which to carry on the work, we have been able at pressures of 20 to 25 pounds above atmosphere or 35 to 40 pounds absolute, to extend the length of service to eight hours actual work without causing any injurious results.

The length of service is not a matter in which any specification can properly treat and the provisions we have always made have been that contractors shall regulate the length of service in accordance with the pressure under which work is being carried on and shall advise his employes fully by notice thereon.

In relation to the period of decompression, notwithstanding all the propositions and suggestions laid down by medical authorities, the specifying or enforcing actual hard and fast lengths of time, are valueless in carrying on practical work. The individual employed has under his absolute control, the period of decompression in the operation of the air valves and in view of the fact that during the period of decompression the temperature is suddenly lowered very greatly, so that the men get chilled through to the bone in coming out from a previous state of free perspiration to the outer atmosphere, we have never found it possible to regulate with any certainty the actual period of time which should elapse in the operation of decompression.

The practical and possible, and the most desirable way in which to regulate this is to instal air pressure with provision for varying stages of pressure, by the introduction of additional air locks, so that there is no single stage involving more than from 15 to 20 pounds reduction in pressure from one stage to the next. In the Hudson River Tunnel, we have invariably used two air locks giving two stages of pressure, more or less equally divided by regulation of safety valves; but we have locks installed that in case of any extremely high pressure being needed, a third stage can be introduced promptly. This arrangement would be perfectly feasible to adopt in caisson construction though as far as I am aware, it has never yet been employed.

The great advantage of this in tunnel work is that a very considerable period of time must elapse in passing from the intermediate to the outer stage of pressure governed by the distance between the air locks, and this permits men not only to equalize themselves to the changing pressure conditions, but enables them to cool off to a material extent after leaving their work before coming to the outer atmosphere.

I have never found regular employes who are willing to remain in the lock one-half of the time which medical regulations call for as necessary; on account, as above mentioned, of the chilling effect of slow outlet from the locks. We prohibit absolutely the use of big valves in locking out men, but with the use of an air lock 6 feet in diameter by 16 feet long, we employ and permit the use of the full aperture of a 1¼-inch valve, and this we consider to be a perfectly reasonable provision for decompression and we have never had any trouble whatsoever in the use thereof. This aperture allows a period of from 75 to 90 seconds per atmosphere.

The effect of rapid decompression often develops "bends," which commonly does not attack the patient until some time after he has left the work.

As a provision against this trouble and against the condition of partial and temporary paralysis, every work of any magnitude whatever should be equipped with a hospital lock on the surface arranged with two stages of pressure, and the lock fitted with cots upon which patients can lie and go to sleep. The hospital lock is also equipped with steam coils and it is seldom that the use of the hospital lock fails to eliminate all trouble of a temporary nature caused by air pressure; usually showing itself in the form of bends or temporary partial paralysis. At the same time some of the cases of temporary paralysis are very obstinate and take a long period of time in which to pass off.

The hospital lock is a most valuable adjunct to the treatment of employes. The use of steam-heated dressing rooms kept at a temperature of 80 to 90° F., and with hot water service to permit of the employes properly and efficiently bathing themselves is also a valuable and necessary adjunct in the maintenance of the health of employes, and the free use of hot coffee furnished to the men, after coming out of pressure, is considered by all persons engaged in air pressure work an absolute essential under modern methods.

In respect to the ventilation, I have before me the records extending over the entire work on Hudson Tunnel and find that at no time under conditions of regular work has the atmosphere shown a greater proportion of carbonic acid gas than eight parts per ten thousand (8 per 10,000), and as a general rule in the regular operation, the proportion does not exceed seven parts to ten thousand.

This is obtained by pumping an excessive quantity of air into the heading and as a general rule the quantity of free air discharged into the tunnel amounts to something like 3,000 cubic feet of free air per man per hour.

The purity of the air we consider usually to be one of the first essentials in maintaining the health of employes. I have recently been engaged in connection with an air pressure proposition for one of our western cities, in preparing specifications, and in these I have provided that the quantity of free air discharged into the tunnel shall at no time be less than 1,000 cubic feet per head per hour, and that the proportion of carbonic acid gas shall at no time exceed nine parts per ten thousand, and that the temperature in the working chamber shall not exceed 80° F., and that, if necessary to obtain this result, the air shall be artificially cooled before delivery into the heading. Regular daily analysis of the air in tunnel heading is part of the duty and equipment of a properly organized engineering corps.

In this particular piece of work, the arrangement for medical examination I consider to be a good one. The work is being executed by the City and under a public commission. This commission employs their own medical man who shall receive a monthly salary and in addition thereto, a fixed specified sum, for the examination of every employe, and this sum is to be charged against and deducted from moneys due to the contractor for the work. I consider this arrangement is a very excellent one, as it keeps the medical examination and supervision of employes in the hands of the public body or company executing the work, and does not leave it absolutely in the hands of the contractor, as is so often the case, with the result that the examination is not regarded or executed as the specifications may provide.

Yours very truly,

J. V. DAVIES.

New York, Jan. 20, 1903.

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Ninety-eighth Annual Meeting held at Albany, January 26, 27 and 28, 1904.

First Day—January 26th.

Unanimous Adoption of Joint-Committee Report.—The morning session of the first day was entirely taken up with the reports of committees, especially with the report of the Joint Committee of Conference appointed for the purpose of consolidation with the Medical Society of the State of New York and the New York State Medical Association. As the agreement came from the Joint Committee it was unanimously adopted, thus practically assuring unification after over twenty years of separation. It was followed in the Comittee's report by the Enabling Act which passed both branches of the New York State legislature last week and was signed by the governor January 21. Of the draft of the Constitution and By-laws for the reunited organizations we give only those parts which are novel and which, because of the fact that they separate the business of the Society from the scientific discussions, promise to be of decided advantage for future meetings.

In moving the adoption of the report of the Committee of Conference and its continuance with power Dr. Abraham Jacobi, of New York City, said that two members of the committee deserved special mention for the work done in settling details of the union: Dr. Henry L. Elsner, of Syracuse, and Dr. Wisner Townsend, of New York City. Dr. Bristow, of Brooklyn, the present President of the Medical Society of the State of New York, also deserved the thanks of the profession of the State for his unofficial but untiring helpfulness in the difficult task of making arrangements that would do justice to all interests. In moving the adoption of the committee's report he said that the new constitution promised to make many difficulties of Society procedure simpler and would surely eliminate that most undesirable factor, an aristocratic class, assuming to themselves the power of the Society.

In seconding Dr. Jacobi's motion Dr. D. B. St. John Roosa, of New York City, said that the time had now come for reunion and he hoped that the report of the committee would be adopted unanimously. The split had not been without its advantages. It had brought with it the question of laws for the regulation of medical practice in New York State much sooner than would otherwise have been the case, and as a result had hastened such legislation in other States also. The separation in New York had also brought about the formation of the Association of American physicians, and that surely must be considered to its credit.

Dr. Roswell Park, of Buffalo, Dr. MacDonald, of Albany, and Dr. Potter, who had been members of the Society in 1882, at the time of division, also seconded the motion, which was unanimously carried with prolonged applause.

The report of the Committee on Public Health had many interesting points, among them especially those with reference to the prevention of infectious diseases.

Prevalence of Typhoid.—During 1903 there were in New York State 25,000 cases of typhoid fever with over 1,600 deaths. Yet typhoid is an absolutely preventable disease. It is now recognized that most of the water courses of the State have become dangerously infected. Even the beautiful clear Adirondack lakes have been known to harbor the bacillus. The only possible safeguard seems to be to make every one take measures to kill the typhoid germs in excreta before they are disposed of in any way; that may eventually lead them into any flowing water. Physicians should insist on this but do not. There is a false impression abroad that exposure to severe cold or being frozen kills typhoid bacillus. Too many sad experiences have already shown that this is a most dangerous opinion and one that must be removed from the minds of all physicians as well as other attendants on the sick.

Vaccination and Life Insurance.—The chairman of the Committee on Public Health suggested that if the life insurance companies, instead of merely asking: Have you been vaccinated? were to add to the question, and When? and then refuse to take risks on persons the interval elapsed since whose vaccination left them liable to contract smallpox, they would not only save money but help to protect the community from this dread disease, which would thus lose most of the human material which it now finds available to carry on its existence and aid its power to do harm.

School Inspection and Hygiene.—Finally the committee's report contained recommendations for the extension of the school inspection system all over the State, since its results have everywhere been most satisfactory. They also suggested the teaching of the means necessary for their prevention. This would be real practical teaching in hygiene instead of the often useless teaching in quasi hygiene that now has a place in the curriculum.

Physiological Therapeutics of Iron.—The scientific session was opened by a paper by Dr. Reynold Webb Wilcox, of New York City, on recent theories of the physiological action of iron and the best methods of administering it. Hemoglobin would seem to be an ideal form for iron administration, yet has not proved so in practice. Most of the so-called albuminates of iron are really compounds of some inorganic salt of iron with albumin. This can be demonstrated by means of nitrate of silver which precipitates the albumose material. Dr. Wilcox does not like the use of the expression iron albuminate for these, but prefers to talk of "massed" iron. Even with regard to this, it must be confessed that our ideas as to its mode of action are most vague and unsatisfactory.

Tic Douloureux Cured.—Dr. Sargent F. Snow, of Syracuse, said that in 20 cases of severe facial neuralgia under his observation all of them were afforded relief of enduring character by the treatment of conditions that had produced increases of intranasal pressure or caused tension within the accessory sinuses of the nose. Many of these cases had had from one or two to all the teeth on one side of the jaw pulled for their pain or had submitted to various surgical operations on the facial nerves. Dr. Snow is of the opinion that the hitherto so frequently considered intractable facial neuralgias will be relieved by proper treatment at the hand of the rhinologist. He is firmly convinced that all hemicrania should be treated on this basis before any other serious measures are tried.

Illustrative Cases.—Dr. John O. Roe, of Rochester, gave the details of some severe cases of facial neuralgia which had been cured by intranasal treatment. One of them had had the facial nerve sectioned with relief from symptoms for two years and then relapse worse than ever. After the removal of a spur on the septum she was better for a time and since the opening of the ethmoid cells with evacuation of pus she has had no further pain. In one of Dr. Snow's cases the Gasserian ganglion had been removed with only temporary relief, while the treatment of a sphenoidal condition brought with it surcease of pain that has now lasted for several years.

Operative Removal of Brain Clot.—Dr. W. C.

Krauss, of Buffalo, said that as a rule the operations for hemorrhage within the skull have had such little success that operators have been discouraged from undertaking them. In this case the patient thrown from a trolley car suffered severe external injuries to his head and shoulder. He recovered so well in forty-eight hours that but for the markings he would have returned to work. Then symptoms of brain pressure began to develop and he had some typical Jacksonian epileptic seizures involving, however, the same side of the body as that of the injury. These began as tremors but finally became true clonic convulsions. There had previously been some aphasia and paraphasia—A confused jumbling of words only, the first few of them intelligible.

Differential and Localizing Diagnosis.—When on consultation it was resolved to bring him to a hospital for operation, the patient proved to have more knowledge of what was going on around him than had been suspected. He refused to go. When the ambulance came he said: "No hospital for me," quite plainly, and later when it was arranged to have a carriage come, as if for a drive, he said distinctly: "You cannot fool me." This made the case look strangely like hysteria, and the idea could not be lightly dismissed, but the character of the epileptic seizures left no room for doubt. Accordingly he was taken forcibly to the ambulance and prepared for operation at the hospital. The incision was made over the side opposite to the injury because the localizing symptoms pointed to that side. Some hemorrhage was found in the membranes of the brain, though only to a slight degree.

Source of Hemorrhage.—The blood had come, not from the middle meningeal artery, as was thought at first, but from some emissary veins in the membranes. There was no fracture of either table of the skull. After the pressure was relieved by the removal of the clot there was one subsequent paroxysmal attack and none since, the patient being discharged with very little sign of the serious operation done, after only three weeks. The hemorrhage was evidently due to the contre-coup of the knock on the skull. The surprise is that the man should have suffered so little from concussion of the brain after the accident, yet have had veins on the opposite side ruptured by the counter-stroke. His personal history, however, that of a man who had drunk considerable quantities for many years would seem to throw some light on this point, as such cases have occurred before in alcoholics.

Enuresis Nocturnal and Diurnal.—Dr. G. E. Beilby presented the results of his study of this subject in some 600 to 700 children at the State Industrial School, in Rochester. Among these children from 4 to 8 per cent. are affected. The ailment is very much more common in boys than girls. Of 75 cases carefully studied these last three years, 71 were boys. Most of the patients were from ten to fourteen years of age, though some of them were from eighteen to twenty-one years. Of these at least 65 would be considered to have sufficient intelligence to exercise proper control of function. There were no vesical irritants, stone or the like, and no rectal irritation present. None of the patients suffered from severe phimosis.

Masturbation and Enuresis.—Dr. Beilby found that in all but 5 cases masturbation was practised. Some of the patients denied it strenuously, but were observed carefully by attendants and later admitted it. This connection between nocturnal enuresis was noted by Jacobi as long ago as 1876. In his article in Keating's Encyclopedia of the Diseases of Children, more than ten years later, he insists on this idea. There seems even to be a direct relationship between the amount of the masturbation and the extent of the enuresis. Careful observations were made in this matter.

Pathological Basis of Enuresis.—The superirritation of the spinal centers for erection and ejaculation lie in the lumbar enlargement of the cord not far from the spinal center controlling micturition. The excitation of one of these centers seems to make the others more irritable. It seems scarcely justifiable to say that there is an actual congestion of this part of the cord produced, though such good conservative authorities as Sir William Gowers seem not to have hesitated to say the practical equivalent of this. In some cases there is also partial loss of control of the defecating center situated in the same region.

Treatment and Prophylaxis.—For prevention the first requisite would be to guard against masturbation. In boys in institutions for many years, especially orphan asylums, it is difficult to assure against knowledge and practice of this vice. Some have considered enuresis nocturna as due to laziness, but the deprivance of drink and the enforced diet would break a boy of this. Cold douches to the spine have done good, but this would seem to be a mental effect. The most effective treatment is circumcision, though it may not be needed because of length or adherence of the foreskin. During the time that the cut tissues are tender there is no masturbation. It is possible thus to break up the habit entirely, but very often boys recur to it. Circumcision also has a strong mental effect on the patients and thus aids in the cure. Certain of the sedative drugs, especially the bromides are of good effect in most cases.

Tuberculosis Toxemia.—Dr. Arthur W. Elting, of Albany, reported a case in which such severe symptoms of toxemia developed that the patient suffered from fever almost as if it were sepsis. Only the cervical glands of one side of the head were involved, but after a time the spleen enlarged and there was a suspicion of Hodgkin's disease. After operation so much toxemia occurred with fever and prostration that the patient's life was despaired of. He recovered completely, however, and even the spleen decreased in size. For the removal of the glands the sternocleidomastoid muscle was cut, and after the operation sewed. In spite of the severe after-symptoms there was never any sign of infection of the wound. The surprise of the case was the amount of toxins from a single absolutely localized infection that showed no tendency to become disseminated even when the patient was worst.

Dilated Urachus.—Dr. C. F. Timmerman, of Amsterdam, reported the case of a woman who after a difficult labor suffered from severe hemorrhages. These continued occasionally and stypticin was found to be a valuable agent for their relief. The development of a tumor in the lower abdominal region led to peritoneal section during which in spite of all the usual precautions the bladder was twice opened. The woman recovered from her operation, and other symptoms improved. At a subsequent labor, however, she died from placenta previa. At autopsy it was found that there were two receptacles for urine connected by a narrow passage. The upper one capable of containing one to one and one-half pints of urine was evidently the remains of the urachus or persistent allantoic stalk

dilated. This usually becomes a fibrous cord attached to the umbilicus and cases of this kind are rare.

Further Cases.—In discussing Dr. Timmerman's case Dr. Robert F. Weir, of New York City, said that he had seen two of these cases of persistent urachus, but that this specimen was a very striking example. In one of his cases there had been a connection with the bladder and the little compartment contained urine. In the other the urachus formed a retention cyst. The mucus from the mucous lining evidently accumulates to form its contents.

Insufficiency of the Pylorus.—Dr. Mark I. Knapp, of New York City, said that stomach specialists sometimes find, when they are about to withdraw a test meal after the usual amount of time has been allowed to elapse, that there are no remains of the meal in the stomach. Many reasons were given for this, Boas' explanation that an increased mobility of the stomach had caused the food materials to pass on to the intestines being very generally accepted. Dr. Knapp has, however, suggested as another explanation insufficiency of the pylorus. He detailed some illustrative cases, and believes that after a time this insufficiency may be followed by such increase of the muscular tissue in the effort to make up for the failure of function that stenosis of the pylorus may result. It is this condition of contraction of the pylorus that is responsible for dilatation of the stomach and not the so-called atony of the gastric walls which used to be considered its cause.

SYMPOSIUM ON DIABETES.

The first paper was by Dr. R. M. Pearse of Albany and contained a review of the recent advance in our knowledge of the pathology of diabetes.

Pancreatic Diabetes.—For over one hundred years there have been references in medical literature to diabetes associated with lesions of the pancreas. Bright's classical case with cancer of the head of the pancreas is only an example. New growths and calculi were pointed out as the usual causes. The French especially accepted this idea of pancreatic diabetes, but the Germans did not until after Von Mering and Minkowski's classical experiments by which they showed that removal of the pancreas caused diabetes and eventual death in dogs. In these depançreatized animals diet did not prevent the diabetes, and starvation did not put a stop to it. After these observations pathologists began to notice special conditions of the pancreas in human subjects dead from diabetes. Hanselmann found a special sclerotic change, but it remained for Opie here in America to point out the true pathology of most cases of diabetes.

Islands of Langerhans.—These hitherto mysterious structures are now generally recognized as special organs having no definite relationship except by position to the rest of the pancreas. Dr. Pearse has followed their formation in the embryo and considers that they ultimately become, if they are not from the beginning, independent structures. They bear exactly the same relation to the blood current that other ductless glands bear, and the pancreas all around them may degenerate or become sclerosed from overgrowth of connective tissues, yet the islands remain normal. This is the explanation of the number of cases in which apparently all the pancreas has suffered yet no diabetes resulted and as the result of which the rôle of the pancreas in diabetes has always remained more or less obscure and in doubt. Histological examinations will clear up such doubts.

Cancer of the Pancreas.—Malignant neoplasms of the pancreas sometimes cause diabetes and more often do not. Dr. H. S. Pearse, of Albany, has had the opportunity to investigate 23 of these cases in only three of which diabetes had been present, in two constantly, in one intermittently. In practically all of the cases in which diabetes had not occurred the islands of Langerhans were found uninvolved in the midst of pathologic tissues. In the two cases of true diabetes, however, they were completely destroyed by the neoplasm. In the third case with intermittent glycosuria they were found seriously affected. In the first two cases just mentioned there was found the characteristic hyaline degeneration of the islands which is always accompanied by diabetes. The islands of Langerhans practically always remain unaffected in the syphilitic pancreatitis, which especially in children so often gives a hard pancreas, yet without diabetes. If the pancreatic duct be tied, though the pancreas suffers severely, the islands remain intact.

Other Forms of Diabetes.—The diabetes that accompanies hepatic disease in certain cases is well known, but in recent years it has been found nearly always to be associated with disease of the pancreas. This is especially true of the so-called bronzed diabetes of the French in which there is cirrhosis of the liver with blood pigmentary deposit, but this is found also in the pancreas. Liver and pancreas are much more closely associated in pathological conditions than has been hitherto supposed. Diabetes with lesions of the adrenals has been reported, but associated lesions of the pancreas have been found in some cases. Dr. Pearse saw a case in which, besides hyaline degeneration of the islands of Langerhans, there was complete destruction from tuberculosis of one adrenal and partial destruction of the other. In more than one case of diabetes with acromegaly the pancreas when carefully examined has been found affected as well as the central nervous system.

Physiologic Chemistry of Diabetes.—Dr. David Edsall, of Philadelphia, said that the investigation of the true nature of diabetes as a disturbance of metabolism had as yet far from clearing up the problems involved rather added to the difficulty of understanding the alterations of physiology and chemistry produced. For some time the disease was looked upon as a disturbance of the glycolysis of the tissue—a failure to break up sugar so as to use it properly. It was even spoken of as a failure of oxidizing processes, but it is very evident now that there is nothing so simple as this. Pathology has centered on the pancreas recently. Observations show that a mixture of pancreas and muscle brings about a noteworthy destruction of sugar. This is Cohnheim's observation. Hirsch, a woman investigator, has shown that a mixture of pancreas and liver brings about the same result. Her acute criticism of her own work, however, equally applicable to Cohnheim's shows that this may be only a bacterial and not a true tissue fermentative process.

Abnormality of Glycogen Formation.—It may well be that diabetes really consists in some defect of glycogen formation, or it may be due to the absence of material furnished by the pancreas under normal conditions to complete other functions. In birds the extirpation of the pancreas is followed by diabetes. If both liver and pancreas are removed

then diabetes does not occur. Diabetes may also be prevented by section of the spinal cord in the upper dorsal region. In depancreatized dogs starvation does not suppress the diabetes and the animals seem only to differ from the birds in degree not kind of glycosuric tendencies.

Sugar Metabolism.—The consumption of sugar in the system is certainly much more of a mystery than has been hitherto thought. Diabetics differ from each other markedly in their attitude toward sugar-containing foods. Some have no disturbance of their general condition if they use levulose, though always seriously disturbed by dextrose. Various types of diabetics might be arranged according to the effect on them of the three forms of mannose. These differ so slightly from one another that it is only by stereo-chemistry, the arrangements of the atoms within the molecule, that they can be differentiated one from another, yet different diabetics act quite differently to them. Much cruder differences than this have, however, been noted by good observers. Some diabetics can consume potatoes without evil effect in amounts that, according to the extent of their diabetes, would seem to be out of the question, and though they are not able to consume in the same way other apparently similar starch-containing food materials. Von Noorden has found a group of diabetics who do very well on an abundant oatmeal diet. There may then be as large a number of special ferments for various starches within the body as on Ehrlich's theory there are receptors to the cells. What is needed is more clinical study for the differentiation of cases rather than more theories of sugar consumption, of which we are only beginning to know our ignorance.

Medical Treatment of Diabetes.—Dr. Wm. H. Thomson, of New York City, said that he did not use or counsel the use of opium or its derivatives in the treatment of diabetes. They can only do symptomatic good and cannot improve the disease. In Dr. Thomson's experience the only drugs that have been efficient for the relief of diabetes and its improvement so long as treatment was continued, are the so-called intestinal antiseptics. Of these sodium salicylate, sodium benzoate and a considerable amount of alkaline remedies have proved the most efficient. Cod-liver oil has proved almost a specific. Many cases get better of their symptoms and stay in good condition so long as they take cod-liver oil regularly. The remedy is contraindicated in the very start in those who have great distaste for it and in those who live a sedentary life. Two brothers who came under Dr. Thomson's care over twenty years ago are still alive, though their diabetes was of what would be called severe form, and they were under the ages of forty and under thirty-five years when they came under treatment. They have learned to drink cod-liver oil as if it were cream, and it must be taken in large quantities.

Prophylaxis and Individual Treatment.—In those who have a distinct heredity of diabetes, attention should be directed to the diet even before sugar is found in the urine, for hereditary influences play an important rôle in the affection. The individual must always be treated, not his disease. In the obese special care must be taken of the heart. In young persons who come under observation with a severe form of the disease there should be no sudden change of the diet or the result will almost surely be fatal coma. The bowels must be kept freely open. Arsenic, Dr. Thomson considers in the class of antiseptic remedies that benefit in diabetes.

Pathology not Necessary for Success in Treatment.—Dr. F. C. Shattuck, of Boston, said that a knowledge of the pathological basis of a disease is not necessary to find a cure for it. Quinine and mercury prove this and in diabetes the physician has not been helpless because the cause remains a mystery. Not diabetes, however, is to be treated, but the patient. Dr. Shattuck believes in enforcing an absolute diet at once, not shortening the dog's tail a bit at a time. If acetone and diacetic acid are present then any sudden change in the diet is dangerous. After one to two months of strict diet a test of the patient's capacity for sugars should be made. Often it will be found that some starchy foods may be allowed. Bread and potatoes are the best forms in which to allow it, as patients crave these, as a rule. Dr. Shattuck has never found a so-called diabetic bread that remained palatable for any length of time. In one case he found a distinct variation in the starch content of an important manufacturers bread from one year to the next.

Diet and Regimen.—Diet lists are an abomination. Each patient must be a rule unto himself in this matter. The skim milk diet Dr. Shattuck has not employed because it was hard for him to understand how removing the fat and leaving the sugar of the milk was rational. Many patients improved on this diet, probably because the amount of food was thus limited. Quantity is quite as important as quality, and diabetics easily eat too much. In regard to wines Dr. Shattuck considers that Moselle or California Hock, which has practically no sugar, may be allowed. Outdoor exercise, but never to overfatigue, and care for the function of the skin are extremely important. Massage is also beneficial. With care the prognosis of individual cases of diabetes is not as bad as set down in the text-books, and Dr. Shattuck has many cases that have been under his observation more than ten years, some of them up to twenty years.

Diabetes and Non-diabetic Glycosuria.—Dr. Heinrich Stern, of New York City, reported a case in which, after an operation upon the parotid gland some glycosuria developed. Not more than three-fourths of one per cent. of sugar was passed. Two years later, after much mental worry, the same patient came under observation with over four per cent. of sugar in her urine. Under diet and care this was reduced to about three-fourths of one per cent., but could not be made to disappear. While passing four per cent. of sugar the woman was losing weight, was extremely uncomfortable, had a harsh, dry skin and other annoying symptoms. These all passed away under treatment, yet the sugar could not be made completely to disappear, showing that she was suffering from a non-diabetic glycosuria, giving no constitutional symptoms to which, for the time being, was added a true diabetes.

At the evening session of the first day, President Hadley, of Yale, delivered an address on the

Conflicting Claims of General Education and Professional Education.—He discussed the present attempt to cut down the college course from four years to three as sure to end in still further reductions of it till it became a vanishing quantity. College education broadened and made men of the students. The education at the professional schools became too much the handmaids of commercial success. Commercialism is good, but not to excess. The shorter the course of liberal studies the less a man is developed. He has less personal satisfaction in life and he thinks less of

the good of the commonwealth of which he is a citizen. The older, broader education made better lawyers and doctors for the community than the modern specialism. There are now more lawyers with large incomes, but fewer Websters and Calhouns. Physicians of the present day probably realize the same thing as regards old-time doctors and their contemporaries. Broader men are needed, with less of special intensity and less of personal success, but with more of self-development and getting more real pleasure out of life. Anatomy and chemistry learned outside of the professional school will have more influence on the development of the individual than if learned in the medical course. There must be no lowering of professional standards, but arrangements must be made so that students educated in the college departments will receive full credit for work already accomplished. All members of the learned professions must be educated men first and technologists afterward. The sooner the mind turns to its life-work the better. The later a man's horizon becomes limited to the sphere of his life-work the better.

Status of the Medical Expert.—In the President's Address, Dr. Algernon Bristow, of Brooklyn, described the present unfortunate state of affairs as regards medical expert testimony and suggested, since lawyers would not agree to the abolition of the present system, which tempted unworthy members of a great profession to drag its name in the mire of shame, that before a physician should be able to qualify as a medical expert he should be in practice at least five years, and should pass a special examination on matters selected by the State Board of Examiners. Until this arrangement came into force experts might be only those who were teaching at medical schools or had been in practice for twenty years.

At the President's reception, held at the Hotel Ten Eyck, just before the annual banquet, by special invitation of the retiring president, the members of the Joint Committee of Conference for the Consolidation of the State Medical Society and the State Medical Association received with him as a public acknowledgement of the reconciliation so nearly concluded.

The officers for the ensuing year are: President, Hamilton D. Wey, of Elmira; Vice-President, Joseph D Bryant, of New York; Secretary, Frederic C. Curtis, of Albany; Treasurer, O. D. Ball, of Albany.

(To be Continued.)

THE SOCIETY FOR EXPERIMENTAL BIOLOGY AND MEDICINE.*

Fourth Regular Meeting, held December 16, 1903.

The President, S. J. Meltzer, M.D., in the Chair.

Reports of original investigations were offered as follows:†

The Changes in the Viscosity of the Blood Produced by Various Experimental Procedures.—Paper by Dr. Burton-Opitz, who described and demonstrated the apparatus used in determining the viscosity of the blood. This demonstration was followed by a discussion of the changes in the molecular friction of the blood after intravenous injections of distilled water, saline, dextrose and alcoholic solutions. The effect of alcohol, when introduced into the stomach and small intestine, was also noted. Next were considered the changes following subcutaneous administration of curare and the differences in the viscosity of arterial and venous blood. K, the coefficient expressing the viscosity, was determined before and after each experimental procedure, two or three determinations being made in each case. It was found that, if distilled water, in quantities of from 5 to 50 c.c., is slowly allowed to flow into the facial vein, the viscosity of the blood is increased, but the increase is not considerable. The following experiment may serve as a sample: The normal coefficient K, in a dog weighing 19.2 kilos, was 802.6, or 5.8 times greater than K for distilled water at 37° C. After the injection of 10 c.c. distilled water the coefficient showed the value 786.0, or 6.0 times greater than distilled water at 37° C. Normal saline solutions produce the reverse effect, *i.e.*, the blood becomes less viscous. In one case after injecting 10 c.c. of 0.7 per cent. NaCl solution, the viscosity of the blood fell from 5.9 to 5.6 times that of distilled water at 37° C. Concentrated solutions of dextrose (5 c.c.) injected into the facial vein, bring about an increase in the viscosity of the blood which is more pronounced than that produced by distilled water. About half an hour after the injection the coefficient K shows again its normal value. If from 3 to 5 c.c. of 10 per cent. or 25 per cent. solutions of alcohol in water are allowed to flow into the facial vein, the molecular friction of the blood becomes greater. The same result can be obtained by introducing the alcohol directly into the stomach, or duodenum. Thirty cubic centimeters of a 25-per-cent. solution were injected into the stomach. The viscosity determined twenty minutes later showed the value 608.09, as against 664.17, the normal coefficient. Thus, instead of being only 7.0 times greater than that of distilled water at 37° C., it changed after the injection to 7.7 times greater. An equally decisive change occurred after injecting 40 c.c. of a 25-per-cent. solution into the duodenum. A marked increase in viscosity also follows subcutaneous administration of curare; however, this result is not evident until the respiratory muscles become paralyzed. Venous blood is slightly more viscous than arterial, but the difference is often very insignificant. In all these determinations a direct parallelism exists between the viscosity-values and the specific gravity. When the viscosity increases, the specific gravity increases also, and vice versa. Not a single exception to this rule could be found. The viscosity was also determined in a dog having very large thyroid bodies. The right gland weighed 57, the left 52 grams. The viscosity-coefficient, obtained by eight determinations, showed the value 1233.17 (specific gravity 1,05028) which means that the blood of this animal was only 3.8 times more viscous than distilled water at 37° C. The lowest previous value obtained by Dr. Burton-Opitz, occurred in a dog after three days of hunger. K equaled in this case 1110.3 (4.2 times more viscous). In general it may be said that the less the viscosity, the longer the period required for extra-vascular coagulation. This was especially well shown in the case just mentioned. Clotting set in after about fifteen minutes.

Survival of an Animal After Removal of Both Suprarenal Capsules, Due to a Previous Grafting of the Organ Into the Kidney.—This paper was reported by Dr. S. J. Meltzer for F. C. Busch and Charles van Bergen, of the Department of Physiology at the University of Buffalo.

Dr. Meltzer stated that in several instances survival of a part of suprarenal grafts was obtained after transplantation into the kidney of the same animal. In one experiment the animal (a rabbit) survived, after apparently all other suprarenal tissue, aside from that

* Proceedings reported by the Secretary, William J. Gies, M.S., Ph.D., New York.

† The abstracts here given have been prepared by the authors themselves. The secretary has made only a few abbreviations and minor changes.

which was grafted into the kidney, had been removed. In this case, after total removal of the left suprarenal a part of the gland, including medulla and cortex, was introduced through an incision into the cortex of the left kidney. Eighty-six days later the remaining right suprarenal was also removed *in toto*. The animal survived the operation and was apparently normal for twenty-one days, at the end of which time it was killed in order to examine the graft. This was found, upon histological examination to have been in part replaced by connective tissue. The surviving cells apparently belong to the medullary portion of the suprarenal. The cortex had been replaced by connective tissue. Blood supply was good. Slides showing the successful grafts were exhibited under the microscope. In this connection, also, Dr. Meltzer showed, under the microscope, a section of Zuckerkandel's organ, the chromophilic bodies of which are similar in nature to the chromophilic granules of the medullary portion of the suprarenal capsule.

On the Absence of a Cane Sugar Inverting Enzyme in the Stomach.—It was shown by Professor Lusk that free hydrochloric acid and not an enzyme caused the inversion of cane sugar in the stomach.

A New Head Holder for Rabbits, with Demonstration.—Frederic S. Lee.

The following reviews were made:

The Action of Potassium Cyanide Upon the Unfertilized Egg.—Paper by Holmes C. Jackson. Loeb and Lewis were the first to note the fact that unfertilized eggs (of the sea urchin), when placed in $\frac{n}{1000}$ KCN solutions, retain their capability of fertilization much longer than when suspended in normal sea water. This was ascribed to the action of the KCN in inhibiting intracellular autolytic processes which lead normally to maturation and finally death. The bactericidal action of KCN was excluded, as the result of experiments in which eggs apparently died as rapidly in sterile as in putrid sea water. Gorham and Tower's experiments, in the same connection, indicated, on the other hand, that the effect of KCN was entirely bactericidal. The sterile eggs retained their capacity for fertilization longer under absolutely sterile conditions than when placed in $\frac{n}{1000}$ KCN. As the question now stands, there exist two almost identical series of sterilization experiments by two pairs of investigators with results diametrically opposed to each other. Critically considered, the more carefully conducted experiments seem to be those by Gorham and Tower; and in the lack of further evidence in favor of an intracellular action of KCN in this connection, we must conclude that the destruction of the bacteria by the KCN removes the condition which causes the death of the cell, and in the absence of which the eggs retain their potential power for growth after fertilization.

Results of Recent Investigations in Proteid Chemistry.—Paper by P. A. Levene. Recent work on the chemistry of the proteid molecule has furnished explanation of many biological phenomena. Thus, in certain pathological conditions there appears in the urine a sulphur and nitrogen containing substance, cystin. The source of the substance in the organism had been unknown, until, through the efforts of Mörner and Embden and others, its radical was demonstrated to be a normal constituent of the proteid molecule. The chromatin of a developed cell differs from that of an unfertilized egg by the presence in it of radicals of purin bases. It is probable that these bases are derived from the histidin radical, which is also a normal constituent of proteids. Hemoglobin is known to be absent from the unfertilized egg and it appears only in course of development of the embryo. It was shown recently that the non-proteid part of hemoglobin is a pyrrol derivative, and it is probable that a pyrrol radical is present in the proteid molecule. Chlorophyl is also a pyrrol derivative, a fact further establishing its close relationship to hemoglobin. The work of Emil Fisher points to the way in which the various component radicals may combine in order to form the proteid molecule, and makes probable the eventual synthesis of true proteid material.

NEW MEMBERS.—The gentlemen named below were elected to membership: A. C. Abbott, Isaac Adler, B. H. Buxton, J. McK. Cattell, H. L. Cushing, E. K. Dunham, Simon Flexner, Reid Hunt, Hugo Münsterberg, J. A. Murlin, Horst Oertel, E. L. Opie, Theobald Smith, A. B. Wadsworth, R. S. Woodworth, Naohidé Yatsu.

BOOK REVIEWS.

PHYSICS AND INORGANIC CHEMISTRY. A Manual for Students and Practitioners. By ALEXIUS MCGLANNAN, M.D., Associate Professor of Physiological Chemistry, Instructor in Clinical Laboratory, College of Physicians and Surgeons, Baltimore. The Medical Epitome Series edited by V. C. Pedersen, A.M., M.D. Lea Brothers & Co., Philadelphia and New York.

IF a medical student wishes a pocket-book on physics and chemistry to help him pass his examinations, this is the one for him. More matter could not easily have been condensed into such small compass; its extreme brevity, however, makes a course of lectures or laboratory work imperative for its understanding. Of X-rays the unmodified statement is made that they have the property of "passing through substances opaque to light." Of antidotes in barium poisoning, the author says "soluble sulphates precipitate barium sulphate in the intestinal tract." Why not also in the stomach? Sodium carbonate is given first place as antidote to nitric acid, though we are afraid the carbon dioxide gas disengaged may prove troublesome. Under cryoscopy nothing is said about the blood or any other liquid except the urine. The paragraphs on valency are types of the combination of brevity with obscureness; their words mean nothing except to one who already understands the subject. But, after all, an epitome cannot be a complete text-book, and this certainly well lives up to its title of "medical epitome." Among its worthier features we note the listing under each chemical of its pharmacopœial preparations, and the addition to the important poisonous elements of "toxicology and tests." As a brief scheme for examination review it is as good as the best.

NOSE AND THROAT WORK for the General Practitioner. By GEORGE L. RICHARDS, M.D., Fellow American Laryngological, Rhinological and Otological Society; Otologist and Laryngologist Fall River Union Hospital, etc. International Journal of Surgery Company, New York.

THIS book, based principally on the author's own experience, is intended as a working guide for those with little experience in the treatment of nose and throat affections. And we are pleased to see that the author talks about his treatment, not in the perfunctory manner of so many treatise writers, nor in the "complete" manner of those who must give every kind of treatment ever used, but as if he believes that you are going to use his treatment in your very next case, and you really want to know just what to do. In tonsillar hemorrhage he avoids the use of hemostatics, such as

alum, Monsell's solution, etc., but recommends hydrogen peroxide, hot water or ice. He always has a long hemostat in his tonsillotomy outfit for a vessel which is spurting. We agree with him that the acute inflammations of the antrum commonly tend toward recovery, and warn against too much readiness to pull a tooth or operate in these conditions. The illustrations, mostly selected from foreign works, are poorly printed. More of them should have been included in the section on the throat. The paper, printing, etc., have a cheap appearance quite in contrast with that of most of the medical books of to-day.

A Text-book of Obstetrics. By Barton Cooke Hirst, M.D., Professor of Obstetrics in the University of Pennsylvania; Gynecologist to the Howard, the Orthopedic and the Philadelphia Hospital, etc. Fourth edition, with 746 illustrations. W. B. Saunders and Company, Philadelphia, New York and London.

As almost all the diseases of women are consequences or complications of childbirth, their preventive treatment is in the hands of the obstetrician. This is the keynote of the present revision, and the author, himself a noted gynecologist, has devoted much attention to the diseases of the genital organs associated with or following childbirth. In addition the recent literature has been reviewed, and changes and additions made with a mind always for the more ready cure of the patient. In a previous review our appreciation of this highly illustrated book was manifested. The author discusses at some length the propriety of attempting to relieve the suffering of the second stage, and believes that it is only humane to do so as far as is possible without interfering with the labor. He considers ether "an efficient, convenient and satisfactory agent" for this purpose, advising that it be used only a few drops at a time, only when the pains come on, and only to produce analgesia not anesthesia. For convenience of administration, ease of control and lack of unpleasantness to the patient, we think that most obstetricians prefer chloroform. To avoid lacerated perineum his advice, if it is evident that the vulvar opening must be torn, is to nick the sides of the vulva rather than let the perineum tear perhaps into the rectum. He sometimes waxes sarcastic over the bungling obstetrical work so often seen. The illustrations are all that could be desired and are well-executed, and the book as a whole is one that it gives us pleasure to commend.

A Manual of Hygiene and Sanitation. By Seneca Egbert, A.M., M.D., Professor of Hygiene and Dean of the Medico-Chirurgical College of Philadelphia, etc. Third Edition, Enlarged and Thoroughly Revised. Lea Brothers & Company, New York and Philadelphia.

For a brief real hand-book of the important subjects that it treats, there is probably no manual of hygiene that is as complete and as practical as this handy five-hundred-page volume of Professor Egbert's. It is really surprising how completely such technical subjects as the antitoxin theory, Ehrlich's lateral chain theory, immunity and our limited knowledge of toxins and ptomains are discussed. The chapters on personal hygiene, on school hygiene and on military hygiene deserve to be read not alone by physicians but by everyone interested in these special subjects. In the chapter on personal hygiene occurs the very apt quotation from Fothergill with regard to the use of alcohol that is very pat at the present time. "First, never have alcohol in the brain when it has work to do; second a little alcohol betwixt a man and past trouble is permissible, but it is not well to put alcohol in front of a coming trouble." The quotation is worth remembering in the light of recent discussions as to the physiological effects of alcohol. Dr. Seneca's book deserves the popularity that has brought it into a third edition within a few years.

Transactions of the Southern Surgical and Gynecological Association. Vol. XV. Fifteenth Session, held at Cincinnati, Ohio, Nov. 11, 12 and 13, 1902. Edited by W. D. Haggard, M.D. Published by the Association.

These transactions contain their usual quota of interesting papers and discussions. H. H. Young contributes a dissertation in the surgery of the lower ureter, which contains much that is new and valuable. G. H. Noble describes a method of perineorrhaphy intended to reproduce the pelvic floor more perfectly, and a method for repairing complete tears, which diminishes the risk of infection from the rectum. The same author, A. H. Ferguson and F. F. Simpson each publish different plans of employing the round ligament in correcting malpositions of the uterus. The volume embraces reprints of thirty papers.

A Laboratory Guide in Urinalysis and Toxicology. By R. A. Witthaus, A.M., M.D., Professor of Chemistry, Physics and Toxicology in the Medical Department, Cornell University. Fifth edition. Wm. Wood & Co., New York.

Primarily intended as a working guide for the author's students, this little volume has found a much wider sphere of usefulness. It gives in condensed form schemes for carrying out qualitative analyses of inorganic substances; a fairly complete review of urinalysis and the outlines of toxicology. It forms a convenient means of refreshing the memory on these subjects and the semitabular form of arrangement makes it convenient for reference.

BOOKS RECEIVED.

The Medical News *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* Medical News *will shortly appear.*

Mt. Sinai Reports. Vol. 3. Edited by Dr. M. E. Brill. 8vo, 572 pages. Illustrated. New York.

VOL. 84. NEW YORK, SATURDAY, FEBRUARY 6, 1904. NO. 6.

ORIGINAL ARTICLES.

SOME OF THE PHYSICAL PROPERTIES AND MEDICAL USES OF RADIUM SALTS; WITH REPORT OF FORTY-TWO CASES TREATED BY PURE RADIUM BROMIDE.*

BY FRANCIS H. WILLIAMS, M.D.,

OF BOSTON, MASS.;

VISITING PHYSICIAN AT THE BOSTON CITY HOSPITAL.

THE keen interest which has been aroused by radium seems to make it desirable to give a report of progress concerning this new substance, rather than to wait for the more complete statement that would be possible if further time were given to the study of its action on skin diseases and new growths, and in other ways. I have, therefore, yielded to the kind solicitation of our President that I should read a paper at this time.

The discovery of the X-rays in 1895 was followed by that of the Becquerel rays in 1896. Becquerel found that uranium and its compounds emitted rays that acted on photographic plates enclosed in paper envelopes, and rendered the gases they passed through, air for example, a better conductor of electricity. To substances that gave out radiations of this character Mme. Curie gave the name "radioactive," and she demonstrated that the radioactivity of uranium and its compounds was an atomic property. Believing that this property did not belong to one class of matter only, she tested a large number of metals, metalloids and minerals, and compared their radioactivity with that of uranium.

In the course of this investigation she found some minerals, among others pitchblende, that were much more radioactive than was to be expected from the uranium present in them, and from this fact she inferred that they must contain a new substance, in small quantities, that was intensely radioactive. After long and careful work, Prof. and Mme. Curie, in conjunction with M. Bémont, succeeded in extracting from pitchblende the substance they named radium. Later Mme. Curie isolated the pure chloride of radium and determined the atomic weight of radium as 225, a figure which she considers exact within a unit. Demarçay determined the spectrum.

The radioactivity of different qualities of radium salts is determined by reference to uranium as a unit, that is radium has a radioactivity of 1,000 or of 7,000 for example, which means that this radium is respectively 1,000 or 7,000 times more radioactive than uranium. The pure radium chloride is said to have a radioactivity of about 1,800,000; the amount of radium of such quality is small.

For practical purposes the strength of a given specimen of radium may be roughly measured by its power to penetrate iron. By means of this test, the purchase of a poor quality may be avoided. The specimens of pure radium bromide that I have render a barium platinocyanide screen distinctly fluorescent when 6.25 cm. (2½ inches) of iron are placed between them and the screen.

The *salts* only of radium, chloride or bromide, are used; metallic radium, like sodium, being unstable in the air.

*Physical Properties of Radium.**—Radium has five properties that especially deserve notice, which obtain constantly without appreciable loss in weight: (1) It maintains a temperature above its surroundings under thermal insulation; a temperature of 1.5° C. has been observed. (2) It is luminescent. (3) It is a spontaneous source of electricity. (4) It gives out three kinds of rays, named by Rutherford, alpha, beta, and gamma. (5) It produces in surrounding objects what Mme. Curie has called "induced radioactivity," what Rutherford has termed "excited radioactivity," and Soddy now designates as "imparted radioactivity." With our present knowledge of the subject, this latter word seems the most appropriate. This imparted radioactivity is caused by what Rutherford has named "emanation."

It is not necessary to discuss the first three properties of radium, but a few words concerning the last two will be useful.

Rays from Radium Salts.—The alpha rays constitute the largest part of the radiation. They are easily absorbed and are slightly deflected by a strong magnetic field. The beta rays are not so easily absorbed as the alpha. They are more strongly deflected by the magnetic field than the alpha rays, and in a different direction, but in the same direction as cathode rays. The gamma rays are the most penetrating of the three kinds of rays. They are not deviated by the magnetic field. (See the following diagram, taken from Mme. Curie's thesis, which shows the three types of rays and the effect of an electromagnet upon the alpha and beta rays.)

The rays from radium increase the electrical conductivity of gases, excite phosphorescence and fluorescence in certain substances, act on a

*Read at the meeting of the Boston Society of Medical Sciences, December 15, 1903.

At this meeting pitchblende was shown. The luminescence of preparations of radium salts of the radioactivity of 1,000, 8,000, and upwards of 1,500,000 (pure radium bromide) respectively, together with the power of these salts to excite fluorescence and phosphorescence, and to increase the electrical conductivity of the air were demonstrated. The ability of pure radium bromide to penetrate thick masses of copper and iron was also demonstrated. The beta and gamma rays were separated by means of a powerful electromagnet. The spintharíscope was shown. Lantern slides made by radium rays were not shown for lack of time.

*The history and physical properties of radium are drawn for the most part from the thesis of Mme. Curie, "Recherches sur les substances radioactives," presented to the Faculty of Sciences of Paris, 1903, a copy of which I obtained in Paris through the kindness of Dr. Bèclére.

photographic plate, and produce both harmful and beneficial effects on animal tissues.

Emanation.—The emanation, which is thought to be a gas, imparts radioactivity to objects that have been in the neighborhood of radium salts for a sufficient period: that is to say, these objects, even after removal from the radium, give out rays for a certain length of time.

Fig. 1.

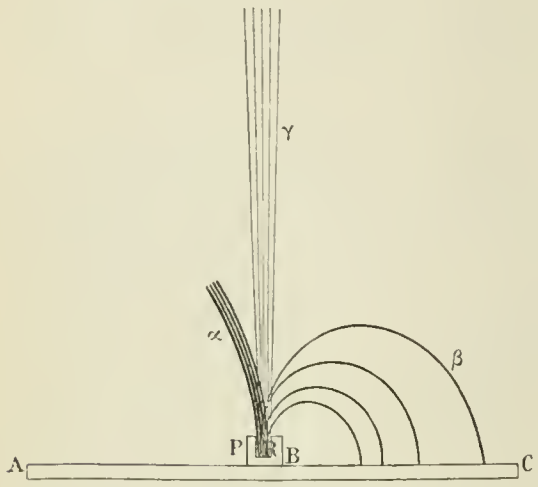

Diagram taken from Mme. Curie's thesis of 1903, illustrating the manner in which the alpha and beta rays are deviated by a powerful electromagnet.

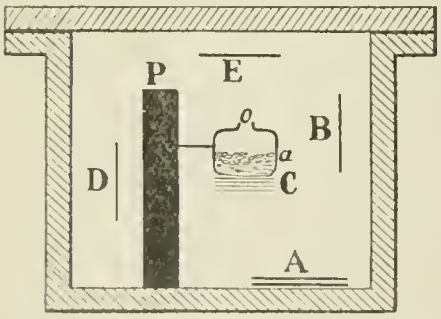
The following diagram is given to show the conditions under which the emanation acts.

If the unstoppered flask *ao*, containing radium salts, is placed in a closed receptacle and kept there for a day, the plates A, B, C, D, E, become radioactive. If, however, the flask is stoppered,

Fig. 2.



Cut taken from Mme. Curie's thesis of 1903, illustrating the manner in which radioactivity is imparted to surrounding objects by emanation.

no radioactivity is imparted to these plates. This experiment, described by Mme. Curie, shows that the *rays* do not play a direct part in the production of the imparted radioactivity, for the plate D, which is protected from the radiations by the thick lead screen P, is made precisely as radioactive as the plates B and E; the radiations can pass through the glass; the emanations cannot. The radioactivity of a plate increases with the length of exposure up to a certain limit, is the greater up to a certain limit the stronger the radium, and disappears in the process of time when withdrawn from the action of the radium.

Radioactivity is imparted more readily when the radium salts are dissolved in water than when they are in a solid state, as in the solid condition very little of the emanation escapes, whereas in the former case it escapes as fast as it is produced. The emanation, when removed with the air from the receptacle containing the radium salts in solution and stored in an air tight vessel, disappears at a definite fixed rate. The radioactivity imparted by the emanation also disappears at a fixed rate.

Mme. Curie states that certain substances, such as rubber, celluloid, paraffin, etc., retain the radioactivity imparted to them longer than can be accounted for by the general law, that they seem to become charged with radioactive energy, under the form of emanation, which they lose gradually while imparting radioactivity to their surroundings. This may make rubber useful in treating certain diseases, as I shall point out later.

The foregoing is a brief statement of some of the physical properties of radium salts, a knowledge of which forms a necessary prelude to their intelligent use in medicine.

We will now consider radium salts from a medical point of view; they may be of service in two ways: First, by their rays; second by their emanation. Let us first discuss the rays and consider what their value may be (A) in diagnosis and (B) in therapeutics:

A. The rays from radium, unlike the X-rays, cannot be used for diagnosis or prognosis, either by means of radiographs or of the fluorescent screen, on account of their inability to show sufficient differentiation between the tissues; therefore, for these purposes they cannot replace the X-rays.

The X-rays, as you are aware, show with wonderful clearness, by means of radiographs, fractures and diseased conditions of the bones; make evident the presence of most varieties of calculi, whether in the kidneys, ureters or bladder, and demonstrate certain conditions obtaining in the chest. By means of the fluorescent screen, they enable the physician to observe, for example, the expansion and contraction of the lungs by watching the excursion of the diaphragm, to observe the position of the heart and follow its pulsations distinctly. By the aid, therefore, of these examinations the practitioner is assisted, for instance, to make an early diagnosis of tuberculosis of the lungs, and to recognize aneurisms in certain cases in which a diagnosis could not otherwise be made. In a word, an examination of the chest is not complete unless it has been looked into by the aid of the X-rays.

To illustrate the inability of radium salts to do this work, I have taken radiographs of a frog, both by the beta and gamma rays together and by the gamma rays alone. The radiographs taken

by the former process showed *no* differentiation between the tissues, and those by the gamma rays alone only slight indication of the bones. The same frog taken by the X-rays showed beautiful differentiation of the tissues, and the time of exposure required was about $^1/_{30,000}$ as long as was necessary for taking the radiographs by radium.

If considerable amounts of radium salts could be used, the rays would then arise from so large an area as to prevent definition, and the improvement in differentiation would be so slight as to be negligible.

Satisfactory radiographs of solid metallic objects, such as keys, can be obtained by radium rays, however.

B. Radium is of value as a therapeutic agent.

The first person, so far as I am aware, to appreciate that radium salts would probably be of service in the treatment of certain diseases was Dr. William Rollins, of Boston, who has done so much to promote the use of the X-rays. Between two and three years ago Dr. Rollins put into my hands a metal box with an aluminum front, containing some chloride of radium, with the suggestion that I use it for therapeutic purposes. I did so employ it, but at that time the radium to be had was weak and I did not obtain definite results.

During the past summer I have seen the successful work being done in London with radium by Mackenzie Davidson, who most kindly showed me all his patients; and also the work begun in Vienna by Holzknecht.

The use of radium salts for therapeutic purposes needs much the same kind of experience as is required for the successful therapeutic use of the X-rays. As with the X-rays, caution must be observed when treating patients, for the sake both of the patient and of the practitioner, for radium if not properly protected, causes severe burns, which do not manifest themselves for a week or more. These burns are painful and heal slowly. Already a number of cases of injury to persons working with radium have been reported.

Precautions.—Radium, therefore, should be kept in a metal box or capsule with a thin mica front or other suitable covering, so that the radiations may be cut off in all directions except that in which the practitioner desires the rays to proceed. To such a capsule I have attached a long, flexible handle, in order to hold the radium at a distance when applying it. This handle is a protection to the practitioner. When not in use, the capsule should be placed in a thick lead box or tube, so that the radiations may be absorbed.

Radium not suitably protected should not be placed in the neighborhood of photographic plates, as it would injure them.

Method.—The method of using the radiations from radium is simple. If the strongest action of the radium is desired, the metal box containing the salts is placed *on* the part to be treated; in this case the box should first be covered with a thin rubber cot, or other suitable substance, which can be readily removed, so that a new cot may be used for each patient and the old one burned up. By this means, the radium capsule does not come in direct contact with the part to be treated, but is separated from it by this new and clean covering. If a weaker action of the radium salts is indicated, the capsule should be placed at a greater or less distance, according to the needs of the case, the intensity of the rays diminishing as the square of the distance.

Exposures.—It is important to remember that an over exposure of a part may result in a burn, and that this burn may not become evident for some days after the exposure has been made. Further, that the exposures differ for different diseases, even superficial ones. Experience, therefore, is necessary to judge not only of the proper length of exposure, but also of its frequency.

Length and Frequency of Exposures.—Exposures must in some cases be longer, in others shorter, and the frequency with which they are given must vary. In some cases the treatment should be pushed; in others harm rather than good would result from this procedure. The exposure, then, must be adapted to the special case, and further experience is necessary to decide the best for all cases, but as a general rule, it may be said that when the beta and gamma rays of *pure* radium bromide (I have discarded the use of the weaker salts) are used together, for the treatment of superficial lesions, and the radium capsule is placed *on* the part to be treated, the length of exposure should be one-half to two or three minutes, according to what the practitioner desires to accomplish.

Exposures should not be made every day. Two or three times a week seems to me the safer procedure, as by this method an interval is given during which progress can be watched.

An exposure of many hours would be necessary if *weaker* forms of radium are used, that is radium of 1,000 or 8,000 activity, before any special results could be obtained, and these weaker forms would not be efficient as compared with the pure radium, so that they need not be considered. Pure radium bromide is none too strong for the work to be accomplished in certain cases; in those in which the full strength is not necessary, the radium capsule can be placed at any distance desired, and the exposure can also be shortened.

CASES.—Thus far my experience with pure radium bromide comprehends 42* cases, many of which were treated at the Boston City Hospital. Of these 42, 9 are diseases of the skin, namely, 1 case of acne, 2 each of eczema and psoriasis, and 4 cases of lupus vulgaris.

In the one case of acne, each pustule was exposed to the radium through an opening in a sheet of lead foil and healing took place.

In the two cases of eczema, two exposures were

*Since this paper was read I have had further cases of superficial new growths and two cases of lupus erythematosus.

given, and there seemed to be some improvement, but the itching was not relieved. The use of radium was then stopped, and the X-rays applied.

In the two cases of psoriasis, the radium was used for small areas only, to test its efficiency. Healing took place in each of these areas a few days after one exposure.

In the four cases of lupus, the results have been very satisfactory. In one of these cases I selected the area in which the disease was most severe for the employment of the radium, and treated the other parts with the X-rays. The portion to which the radium was applied improved much more rapidly than those for which the X-rays were used. Two of the patients are now apparently well, and the two others, for whom treatment was begun later, are improving. The action of the radium in all these four cases was far more prompt than that of the X-rays.

Of the remaining 33 cases, 1 is a small keloid, 5 are cases of rodent ulcer, 23 of epidermoid carcinoma, and 4 are breast cases.

In the first case, the patient had two small keloids, one of which is being treated by radium and the other by the X-rays. Improvement has taken place in both, but has been more rapid in the one treated by radium.

Two of the 5 cases of rodent ulcer have healed, and three show great improvement. One of these latter cases is an extensive growth that was increasing rapidly and the patient was fast losing in weight and strength. The use of radium was followed by marked and striking improvement locally—although at this stage of the disease the X-rays had not succeeded even in arresting the growth—and the gain in the patient's strength has been most satisfactory. In this case the radium has thus far shown marked superiority over the X-rays.

Of the 23 patients with epidermoid carcinoma, including one case of the auditory canal and one of the tongue (these were not readily accessible to the X-rays), 11 have healed and 12 are improving. Among the latter there is present promise that most of them will heal. One of these is a carcinoma of the lip that had been steadily treated by the X-rays, but did not yield to them, the second case only I have seen during the last four years of carcinoma of the lip which was not healed by the X-rays.

The four remaining cases are breast cases, three of which were originally recurrences after operation; the three latter cases are improving, although certain of them were not doing as well under X-ray treatment.

These cases show that radium is useful for treating some skin diseases, and superficial new growths; in this class may be included diseases of the cervix uteri, for example.

The application of radium, like that of the X-rays, is painless.

In new growths, when there is open ulceration and considerable induration, radium, like the X-rays, causes rather free discharge and the induration seems to melt away. The pain that sometimes accompanies this process is due, I think, to small collections of fluid and seems to be caused by their pressure, as it is relieved after free discharge.

Tests with Beta and Gamma Rays; Use of Gamma Rays Alone.—I am now endeavoring to determine to what depth the healing action of radium salts may go. The method of approach to this question may be of interest to you. The experiments* to be described were made in a dark room with one of my specimens of 50 milligrams of pure radium bromide, and in making them the beta and gamma rays only needed to be considered, as the alpha rays are absorbed by the mica front covering the capsule. The two former used together cause healing in certain superficial cases, as we have seen. To learn whether or not the beta rays could penetrate deeply, I placed the end of my little finger in their path, after I had first separated them from the gamma rays by means of an electromagnet, and I found that under these conditions, even the flesh of the finger cast a marked shadow on the screen. This experiment, together with others that have been made, shows that most of the beta rays are absorbed near the surface and cannot be used to penetrate deeply. Also, while the beta rays were deflected, I put a sufficient thickness of aluminum in their path to absorb them wholly. I then tested the gamma rays with the same thickness of aluminum, to see if it cut off any appreciable amount of these rays, and found that aluminum even several times as thick interposed between them and the fluorescent screen cast no special shadow upon it. In this way I learned the thickness of aluminum required to cut off the beta rays from this specimen of radium, while allowing the gamma rays to pass, and therefore can easily expose a patient either to the rays that act on or near the surface, or can shut off these and use only the rays that penetrate more deeply.

As a further test of the penetrating power of the beta and gamma rays respectively, I placed a barium platinocyanide screen on one side of the body and 50 milligrams of pure radium bromide on the other and found that the gamma rays used alone made the screen fluorescent; that this fluorescence was much increased by the addition of 50 milligrams more of pure radium bromide but that the illumination of the screen seemed to be the same whether the gamma rays were used alone or with the beta. This experiment showed that the gamma rays can pass through the thickest parts of the body and that as we have already seen, the beta rays are more easily absorbed than the gamma.

Another question to answer was whether or not the gamma rays healed, and in order to do this it was necessary to find out the proportion of the beta and gamma rays given off by the radium salts, in order to know what exposure

*I had the privilege of making these experiments in the Lowell Laboratory of Electrical Engineering, of the Massachusetts Institute of Technology.

to make. This I determined by means of my fluorometer,* which showed that there were at least fifteen times as many beta as gamma rays. Therefore it seemed that the exposure given when the gamma rays alone were used must be longer than when they were employed in combination with the beta rays, or that it would be necessary to use a larger quantity of radium. I may mention, by the way, that thus far I have seen no irritation result from an exposure to the gamma rays that was twenty times as long as that given when the beta and gamma were used together. We may infer from this that the beta, rather than the gamma rays, are the ones that cause the burns.

The next step to take in order to determine whether or not the gamma rays could heal was to treat some skin diseases or superficial new growths with them alone. If these did not heal, then the attempt to treat deep seated new growths with radium might be abandoned, and a number of suffering patients be prevented from subjecting themselves to long, anxious, clinical tests in the hands of many practitioners. The trial I am making does not involve detriment to the patient, as it does not delay for more than a short time the use of the beta rays in case the gamma rays alone do not prove efficient.

If the gamma rays are thus used, a sufficient thickness of aluminum must be put over the radium capsule to absorb the beta rays, for if the latter were not cut off, the exposure required for the small proportion of gamma rays given off by the radium would result in a burn from the beta rays.

So far as I am aware, my own cases of skin diseases and external new growths are the first to be treated by the gamma rays alone. Some of these tests are not yet finished, and the question of how much help can be obtained by using the gamma rays only, for treating deep seated new growths, I shall take up on another occasion, but these tests have demonstrated that the beta rays should not be used with the gamma for such new growths.

Radium Rays and X-rays Compared.—It will be interesting to compare the radiations from radium and the X-rays as a therapeutic agent in the treatment of *skin* diseases and *external* new growths. We shall see, I think, that the comparison at the present time is greatly to the advantage of the radium, and quite in contrast with the comparison which was made between radium and the X-rays for taking radiographs or for fluoroscopic examinations. In the first place, when radium is employed for healing purposes no cumbersome apparatus is necessary; radium is portable and always ready for use. Further, the dose from radium is uniform, the strength of the output does not vary, so that the dose depends entirely on the length of exposure and the distance of the radium from the part to be treated. Radium may be applied to parts which are not readily accessible to the X-rays, as the mouth or vagina. Furthermore, the healing action of the radium is more prompt. The treatment, therefore, extends over a shorter period, and fewer exposures are required than when the X-rays are used. Radium has the further advantage of bringing about healing in some cases where the X-rays have failed after careful and long continued treatment by them. On the other hand, the following cuts published in this journal, October 3, 1903,* of a patient whom I treated with the X-rays, illustrate a type of cases in which radium would probably not be of service, at least with the amounts now at our command.

Fig. 3.

Case 78, A. D., twelve years of age. Microscopical diagnosis, lymphosarcoma after first operation and round-celled sarcoma after second operation. Duration, seven years. Before treatment by the X-rays.

Except, however, for certain classes of cases and the present superiority which the X-rays have of being able to cover larger areas than radium, as in cases of extensive psoriasis, the advantage at this time lies chiefly with radium. Of course, I need hardly say, it is yet too early to give a final and definite opinion as to the value of radium salts as a therapeutic agent. Sufficient time has not yet elapsed to enable us to know how permanent the excellent beginnings will prove. The X-rays have had a longer trial and, as we are aware, have done good service, and in regard to permanency of effects in cases of new growths,

*Taken from the third edition of "The Roentgen Rays in Medicine and Surgery," by permission of The Macmillan Company.

for example, have compared well with operation in some cases. For instance, in one of my cases of spindle-celled sarcoma the patient was operated on in June and again in September, 1901. A second recurrence took place in the following December, and in January, 1902, the patient was brought to me for treatment by the X-rays. He is now well and has been well for nearly two years. Still other patients, that had and had not been operated on, are well and have been well for about three years, since their treatment by X-rays.

If the results in treating superficial new growths, for example, with radium are only as permanent as those obtained by the X-rays, this

Fig. 4.

Case 78, A. D., twelve years of age. After treatment by the X-rays.

new agent will be of great service, or if such patients remain well for a longer period than has followed the use of the X-rays, we shall have still greater reason to be thankful to the discoverers of this substance.

Emanation.—The disadvantages under which radium seems to lie as compared with the X-rays, in covering large surfaces, may be only a seeming one, for it is possible that by imparting radioactivity to certain substances, such as rubber and celluloid, we may be able to extend the usefulness of radium. In order to do this, a sheet of rubber or other suitable substance may be made radioactive by exposing it to the emanation of radium, and this radioactive surface may be applied to a considerable area of psoriasis, for example.

Further, the emanation may be of service in treating diseases which are on or near the surface of the respiratory passages, in some such manner as that suggested by Soddy,* for the treatment of pulmonary tuberculosis. Whether or not it is fair to expect that this more deeply seated trouble can be helped by the emanation remains to be seen, but the proposed method does not seem to me to hold out much hope for the cure of this disease.

The emanation may also be used to impart radioactivity to liquids and a given liquid employed externally for healing purposes; or internally as a therapeutic agent, as has been suggested.

In conclusion, my experience thus far teaches me that there is much similarity between the action of the radiations from radium and the X-rays; that if the results obtained by radium prove permanent, this new therapeutic agent will be largely used instead of the X-rays, but that the two will supplement each other.

1. Certain diseases promise to yield more readily to treatment by radium and others to the X-rays.

2. A disease that has attacked different parts of the body of a given patient may be better treated in certain regions by radium and in others by the X-rays.

3. It is quite possible that in some cases the two remedies used together on the same area and at the same sitting may accomplish better results than either alone.

LATE RESULTS OF X-RAY TREATMENT OF SARCOMA.

BY WILLIAM B. COLEY, M.D.,
OF NEW YORK.

I have very little to add to what I have already said in my paper read before the American Surgical Association in May, and yet the later histories of the apparently successful cases cannot fail to be of interest to those who are anxious as I believe we all are to determine the exact scientific value of this new therapeutic agent in malignant disease.

A year ago in a brief paper I attempted to outline the limitations of the X-ray in cancer and I emphasized very strongly that it was folly to characterize as cures cases in which but a few weeks or months had elapsed since the disappearance of the tumors. My own later experience has fully justified this conservatism.

Since February, 1902, I have observed 103 cases of malignant tumors treated with the X-ray: 30 recurrent carcinomata of the breast, 42 sarcomata in various localities, 28 cancer of the head, face and neck; 3 miscellaneous. Most of the cases were treated at the General Memorial Hospital under my direction, by Mr. W. P. Agnew and Dr. James Ogilvie.

* "A Method of Applying the Rays from Radium and Thorium to the Treatment of Consumption," British Medical Journal, 1903, II, 197 199

I will briefly cite the after-histories of some of the apparently successful cases:

Case I.—Sarcoma of the Neck, Pectoral and Axillary Region.—Disappearance under four months' treatment. Metastatic recurrence in four months in abdomen and inguinal region. Growth slowly disappeared under one year's continued treatment. Patient's present condition: small tumor in eyelid; growths elsewhere apparently disappeared. January 8, 1904. Since October innumerable recurrences have appeared in the skin and subcutaneous tissues. More abundant in regions subjected longest to the X-ray. General condition one of rapid failure.

Case II.—Inoperable Round-celled Sarcoma of the Pectoral and Axillary Region.—Entire disappearance under five months' treatment with the mixed toxins and X-ray. Recurrence about four months later; second disappearance under resumption of the same treatment, in February, 1903. Local recurrence in August, 1903. The patient is still taking the X-rays and toxins at the present time.

Case III.—Round-celled Sarcoma of the Back, Recurrent.—Disappearance under the X-ray treatment in the summer of 1902; recurrence four months later, removed by excision; X-ray continued twice a week since, as a prophylactic measure. Patient well at present.

Case IV.—Round-celled Sarcoma of the Femur, Involving Two-thirds of the Shaft.—Amputation of the hip-joint advised in February, 1902; refused by patient and family; has had X-ray treatment almost continually from February, 1902, up to the present time. The local tumor nearly disappeared and there has been no increase since. The femur remains thickened and hard. Examinations of the tissues removed from the sinus failed to show any sarcoma elements. Metastatic growth developed in the pectoral region in December, 1902; partially removed by excision and the remainder disappeared under the use of the X-ray and the mixed toxins. A large metastatic growth developed in the right lumbar and iliac region; this softened under the toxin treatment and a large amount of broken down tissue was evacuated in January, 1903, under ether. The patient's physical condition remains fairly good and there is no marked evidence of a tumor at present, although the sinus in the back has not entirely closed and the one in the femur also remains open. During the last few months his general condition has, I think, slightly deteriorated. He has kindly consented to be present to-day, January 8, 1904. Condition the same.

Case V.—Recurrent Inoperable Carcinoma of the Cervix Uteri.—Case of Dr. Jarman. The patient was treated by Mr. Agnew, under my direction, at the General Memorial Hospital, during the summer of 1902. After a few months' treatment all evidence of the growth disappeared and examination in May, 1903, failed to show any return. She was examined further by Dr. Jarman in October, 1903, and was still free from recurrence.

Case VI.—Carcinoma of the Breast, Deep-Seated, Inoperable, Involving Periosteum of the Ribs and Sternum.—The patient was treated at the General Memorial Hospital for about five months, from December, 1902, to May, 1903, with the result that the tumor entirely disappeared as far as could be made out from external examination. General health has remained good; she has resumed her occupation. Subsequent examination, October 1, 1903, shows a local return of the disease. December 15, 1903. There is no ulceration but a slight thickening in the original site of the tumor. The patient is in perfect health and working every day.

Case VII.—Advanced Hodgkin's Disease with Almost Complete Recovery, followed by relapse at the end of eight months, with speedy death. The patient, Mr. V. B., aged forty-three years, was referred to me by Dr. Frank Hollister on September 25, 1902. At that time he was suffering from far advanced Hodgkin's disease with greatly enlarged glands in the cervical, axillary and inguinal regions. The spleen was very much enlarged covering an area 8½ x 11 inches and extending from the left side to within 2 inches of the right ant. sup. sp. and within one inch of the symphysis pubis. Frequent blood counts were made and these confirmed the diagnosis of Hodgkin's disease. The patient was put upon both the X-rays and toxins and improvement was immediate and very rapid. The tumors of the neck, groin and axilla entirely disappeared and he was able to leave the hospital within three months. The treatment was afterward continued by my associate, Dr. F. R. Cook, until March, 1902. In January he had been able to resume his work. The splenic tumor had diminished to about one-eighth its original size and the patient's general health was good. In April he became suddenly worse, developed a large, hard tumor in the region of the liver and died within a few weeks.

One of the most remarkable cases of sarcoma disappearing under the X-rays, is a case of round-celled sarcoma of the neck, recurrent, which was treated by Dr. E. Rodney Fiske, of Brooklyn. The patient had formerly been under my care and was regarded as entirely hopeless. He was treated by Dr. Fiske in December, 1901, with the result that the large recurrent round-celled sarcoma of the neck and axilla entirely disappeared. I showed him before the meeting of the Academy of Medicine in the spring of 1902. Dr. Fiske tells me that a few months later he had metastatic masses in both groins, which yielded to further X-ray treatment. The treatment was continued with more or less frequent intervals of rest up to the summer of 1903, when he was apparently well. He, however, died rather suddenly on September 23, 1903. The exact cause of his death is not known, but I think there can be little doubt that it was due to internal metastases.

Still another patient with a very large inoperable spindle-celled sarcoma of the abdominal wall, which I had considered entirely hopeless, has been under X-ray treatment by Dr. Clarence I. Skinner, of New Haven, since January, 1902. The treatment has been kept up with occasional intervals of rest up to the present time. The very large tumor, the size of an eight months' pregnant uterus has nearly disappeared and at present (October, 1903) he writes me she is feeling very well and attending to her duties as a school teacher.

This was one of the largest growths that I have ever seen nearly disappearing under the X-ray, but it cannot yet be classed as a cure.

Two patients with deep-seated carcinoma, one of the breast, the other of the sigmoid, were apparently greatly improved, but the later history shows the possibility of the X-ray favoring or hastening a general dissemination of the disease while the local condition is improving. This is a point of very great importance and yet, at present there is hardly sufficient data to enable us to settle it. The patient with the breast cancer was operated upon in July, 1902. The operation was only a palliative one and I was obliged to leave behind considerable infiltrated tissue in the pectoral region. I put the patient on X-ray treatment at once; the pain was relieved; the tissues softened and became normal to the touch and the normal movements of the arm were regained. The treatment was kept up with intervals, for nearly a year. When left off for a few weeks, the patient had neuralgic pains in the pectoral region and in the arm. Her general health was perfect. In May she began to complain of sciatica and lumbago. She lost weight. The pains became exceedingly severe and shifted from one region to another. There was no local return of the tumor, yet, I felt convinced there was a generalization of the disease. This opinion was confirmed by continuous and rapid decline in general health, resulting in death in August, 1903.

In the other case, that of cancer of the sigmoid and rectum, the local condition was greatly improved and the tumor which could be readily felt through the abdominal wall, became much smaller, so that it could no longer be palpated. The treatment was carried out by my associate, Dr. F. R. Cook, from October, 1902, to August, 1903. The patient was able to attend to his work. The pain, which had been very severe before treatment, was scarcely affected by the treatment. The patient's weight remained nearly the same the entire time. Early in August he grew worse rapidly and died in less than a month. It should be stated that, in addition to the X-ray, the mixed toxins were given in this case most of the time by his family physician.

In several cases in which small recurrent nodules appeared in the skin, following operation for cancer of the breast, the nodules all disappeared after a few weeks' treatment. In every case, however, there was a speedy return after the cessation of treatment. In one case a gradual enlargement of the sternum and ribs developed while a small skin nodule was being treated in the same region.

Of thirty cases of recurrent cancer of the breast that have been treated at the General Memorial Hospital or in private, in but a single case has a large and deep-seated growth disappeared after six months' treatment.

Prophylactic Value of the X-ray.—This is a question of great importance and the surgeon will more and more frequently be asked whether it is wise to have a course of X-ray treatment after operation for external cancer. At present I do not think we can answer it in a positive way. It will require a very large number of cases covering a period of many years before we can draw any scientific conclusions. There are too many factors that enter into the problem.

The results of operation for cancer of the breast, for example, differ so widely in the hands of different surgeons, that one might reason from one series of statistics that operative treatment was of value, and from another series, that 75 per cent. of patients were cured. If then, it is difficult to determine the value of operation alone, how much more difficult is the problem of determining the value of operation plus after-treatment with the X-ray.

I believe that there are good theoretical reasons for using the X-ray after operation, and yet, I must confess that my results thus far have not given much practical support to the theory. In one patient, I operated a year and a half ago for double carcinoma of breast and removed both breasts and axillary glands. The wounds healed quickly and well, but fearing a return, I placed her immediately upon regular X-ray treatment, four times a week. At the end of six weeks small nodules appeared in the skin in the vicinity of the cicatrix in the very region of the X-ray exposures, and continued to increase in size under prolonged X-ray treatment. In addition, the patient soon became cachectic and showed signs of generalization of the disease.

In another case of carcinoma of the breast, that of a woman thirty-four years old, with a small growth and slight involvement of the axillary glands, I began the X-ray as soon as the wound was healed, a year ago, and kept it up for six weeks to two months. In about eight months a small nodule developed beneath the skin in the center of the area rayed.

In one of the most recent works upon X-ray therapeutics, a trial of the X-ray is advised before operation in operable cases. I believe such treatment positively dangerous for two reasons: first, a possible temporary improvement is likely to blind the patient as well as the physician to the grave danger of general dissemination, even while the local trouble is apparently decreasing; second, if after a trial of the X-ray an operation is decided upon, the surgeon will be less able to appreciate the full extent of the growth and will be inclined to leave behind infected

tissue. Still again, it has been shown that tissues long exposed to the X-rays often fail to heal well.

One month ago I operated upon a patient with far-advanced epithelioma, involving nearly the entire lower lip. He stated that 1½ years ago he had a small epithelioma of several years' standing. Having been told that the X-ray offered better chances than surgery, he tried the former, and after 13 treatments the growth had entirely disappeared. After a few months it recurred locally and the X-ray treatment was resumed and carried out regularly and thoroughly, fifteen-minute exposures being given, but this time with no effect in checking the progress of the disease. When at last he decided to try other means, the growth was very nearly inoperable and the chances of cure exceedingly slender.

Conclusions.—I think we are already beginning to see the evil effects of the too optimistic reports as to the value of the X-ray in cancer. A year ago, in a paper read in this very room, 50 per cent. of cures were claimed and the use of the X-ray was advocated as a substitute for operation.

Pusey and Caldwell,* in their carefully reported series of cases state that of 27 cases of superficial epithelioma, 21 or 77.7 per cent. are, as far as can be told from present condition, cured. Yet, only 7 were well over eight months and only one as long as fifteen months.

A careful review of all the reported cases of cancer treated by the X-ray, together with a personal experience and observation of more than 100 cases of various forms of malignant tumors, have served to confirm and emphasize the convictions already expressed.

1. The use of X-ray in cancer should be limited to recurrent and inoperable cases, with the sole exception of small superficial epithelioma of the face. Even here, I believe, the results of excision will prove to be better and more lasting, save in the proximity of the eyelids and nostrils.

2. It is most misleading to report as cures, cases in which malignant tumors have merely disappeared under the influence of the X-ray, since speedy return is the rule rather than the exception.

3. At the present moment there is no evidence to prove that any permanent cures have been obtained, save possibly in the case of rodent ulcer.

Aniline Poisoning.—Aniline oil exerts its poisonous influence, says A. Wrzosek (Friedr. Bl. f. gericht. Med., Vol. 54, No. 6), especially upon the blood and central nervous system in both man and animals. The portals of entry may be the lungs and alimentary tract as well as the uninjured skin, while excretion occurs chiefly through the urine, in part as such, in part as paramedophenol. Symptoms of intoxication, such as paresis, complete paralyses, convulsions, tetanus and trismus point to an involvement of the nervous system, while cyanosis, jaundice, hemo- and methemoglobinuria indicate breaking down of the red cells. Anatomical lesions are few and not characteristic.

* Pusey and Caldwell, 1903.

ABDOMINAL VERSUS VAGINAL HYSTERECTOMY.*

BY JOHN B. DEAVER, M.D.,
OF PHILADELPHIA, PA.

Cancer of the uterus is the most insidious and deadly malady of the female genital tract that the surgeon is called upon to treat.

Carcinoma in the female occurs more frequently in the uterus than in any other organ or part of the body and affects the cervix in about ninety per cent. of the cases. Unfortunately, many of the women afflicted with this disease suffer from symptoms ill defined, free from pain and with but little discharge until the growth has become so extensive as to involve the broad ligaments, the bladder or the vagina. For this reason, viz., the absence of leucorrhea and pain, the family physician is often unaware of the real nature of the disease in question until all hope of successful surgical intervention has gone. It cannot be too strongly impressed upon the general practitioner that irregular bleedings from the uterus, whether before, during or after the menopause should be viewed with suspicion and thoroughly investigated. No feelings of delicacy should prevent an inspection of the cervix and palpation of the uterine body, nor a fear of consequences deter resort to curettage in suspected cases with examination of the scrapings for malignancy.

A negative finding by the pathologist should be accepted with great reserve and not allowed to controvert unmistakable clinical symptoms, especially in a woman approaching or past the menopause.

I emphasize the latter because, as is well known, epithelioma rarely begins until after the childbearing period. Many of the cases of supposed hemorrhagic endometritis, with a malignant family history, would be better for a complete hysterectomy. It is the practice of the writer to do a complete removal of the uterus in hemorrhagic endometritis under the circumstances referred to. The question of removal of normal ovaries with the uterus need only be considered when the patient is comparatively young and the disease confined strictly to the uterus and is in its incipiency, when it is the writer's practice to leave one or both.

In cases of hemorrhagic or hypermetrophic endometritis with foul smelling discharge curettage should be practised and the findings examined microscopically. A negative finding by the microscope is not to be considered as an argument against the value of the same as an aid to diagnosis, merely indicating that the curette may have escaped the cancer area or that the latter was situated within the uterine muscle.

In discussing the operative treatment of carcinoma of the uterus we must remember that the surgeon too often does not see the case in the early stages, and must decide whether an operation is feasible and what the chances of eradication of the growth will be.

* Read before the American Association of Obstetricians and Gynecologists, Chicago, September, 1903.

The cervix is the most common site of cancer, is usually squamous celled, and in the beginning is essentially a local process, with a hard and indurated cervix and with papillæ elevated from the mucous membrane. As these papillæ increase and enlarge the cauliflower-like growth so often felt, becomes evident. Ulceration and necrosis follow and the crater-like condition, also too well known, may be felt. In the latter stages the vaginal vault becomes implicated, the broad ligaments, the uterus, the bladder and the rectum involved and of course radical treatment can be of no particular use.

To the surgeon the question must always be answered, whether the excision of the cancer area can be performed by section through normal tissue. Palliative measures for the relief of the discharge, the bleeding, or the pain are better done by local measures than by the use of the knife.

To determine the indications for operation a most careful bimanual examination is necessary. If the uterus is adherent and fixed in the pelvis, the broad ligaments extensively infiltrated and the vaginal vault involved, operation is inadvisable. In my judgment the removal of the greater part of the vagina is inadvisable. Cases where there is such involvement of tissue as to require so extensive an operative procedure do much better by thorough curettage and cauterization, repeated if necessary. Recurrence will surely occur in this class of cases and when the radical operation has been performed new channels for the extension of the cancer are opened up. I have found that the pain consequent upon the recurrence of the growth, following late and extensive operation is greater than in those cases curetted and cauterized.

It is always difficult, however, to decide accurately the extent of the growth, especially in cancer of the cervix, and therefore where reasonable doubt exists an exploratory operation can be decided upon, and the radical operation performed as being the most conservative, whether the carcinoma is located at the cervical or at the fundal end. In the early stages a complete removal of the uterus, broad ligaments and the lymph channels in the latter, should guard against recurrence with reasonable security.

The decision as to the operation, whether to perform the ablation by the vaginal or by the abdominal route will depend, in the early stages, upon the particular predilections of the operator. Personally, I would strongly oppose vaginal hysterectomy for carcinoma of the cervix uteri, except in the presence of obstacles necessitating such a course. For intance, a very stout abdomen, nephritis or, old age. It is the practice of the writer to do a complete hysterectomy by the abdominal route in fundal as well as in cervical carcinoma. The vaginal operation offers no advantages over abdominal section, when the latter is properly and intelligently performed, and suffers from the imputation of being an incomplete operation, dangerous to the ureters and liable at any time to give rise to severe secondary bleeding.

The abdominal operation offers an increased space for necessary manipulation, greater security against hemorrhage from a better exposure of the vessels and lessens the risk of injuring the ureters. The field of operation can be kept constantly in view by the Trendelenburg position and gauze packing, keeping the intestines out of the way of injury, and most important, the ability to better avoid infection. In abdominal hysterectomy we are better able to keep beyond the area of diseased tissue, a larger portion of the broad ligaments together with their lymph channels can be excised and individual glandular enlargement noted and removed.

The ever-present danger of injury to the ureters is not so likely to occur in the abdominal route on account of the better exposure of the structures. Expert operators have occasionally severed the ureters and the introduction of catheters makes any pelvic operation safer, yet I confess I have never introduced them for this purpose.

It is usually claimed for abdominal hysterectomy that a thorough dissection of the pelvis can be made with the removal of the infected glands. The lymphatic system of the uterus consists of a rich network of vessels, those from the vagina and lower portion of the cervix following the uterine vessels to glands at the bifurcation of the common iliac arteries, usually three in number, and thence pass upward. The lymphatics from the body of the uterus anastomose with those of the cervix uteri, travel downward to the deep inguinal glands by way of the round ligaments and pass through the utero-ovarian ligaments emptying into the lumbar glands. Yet, with this abundant lymphatic supply, carcinoma of the uterus spreads by continuity of tissue more readily and rapidly than through lymphatic metastasis.

I do not believe that the necessity exists to dissect out the iliac glands, as the additional mortality from operation is not repaid by lessened recurrence. Such enlarged glands as I have removed have been found to be inflammatory and not malignant, and in the event of cancer of these iliac glands the case has become incurable by reason of extensive infiltration of tissues adjacent to the uterus.

Extension downward into the vaginal epithelium, forward into the bladder and backward to the rectum, is much more common than metastasis into the pelvic glands. Epithelioma of the vagina is sometimes overlooked as a point of metastasis or implantation, as the diseased area frequently resembles an excoriation, such as could have occurred in the preparation for operation. Extension into the bladder may be unrecognized, except by means of a cystoscopic examination.

In performing abdominal hysterectomy for

carcinoma I first curette the cancer area, and cauterize with pure carbolic acid, and then re-cleanse the vagina thoroughly. It may be necessary in some cases where oozing persists to tightly sew the cervix, if the cautery fails to check such bleeding. I do not make a median incision in the abdomen, but prefer to incise through either rectus muscle close to the median line, thus avoiding hernia, one of the so-called disadvantages of the abdominal route. In performing hysterectomy I use the usual technic and methods of others, with possibly a few variations. After removing the uterus the bleeding edges of the vagina are whipped over by a lock suture. Gauze drainage is introduced into the vagina from above downward and allowed to project slightly into the pelvis when the peritoneal flap from the anterior surface of the uterus, which carries the bladder wth it, is brought over the projecting gauze and stitched to the posterior wall of the vagina; in this wise completing the operation as an extraperitoneal one. The abdominal wound is closed by tier suture.

The cautery knife of Downs is used and extolled by a few operators, first, because it renders the operation bloodless and secondly, that its ultimate results are presumably better in carcinoma cases. I have always been satisfied, however, with my results by the use of suture and ligature and those cases calling for the cautery to destroy tissue are not ones adapted to radical operation. I might add that a multiplicity of instruments, awkward to handle and which tend to make a complicated out a simple operation, is to be deprecated. The more ideal results obtained in delicate operative procedures often depend upon a simplicity of technic, few instruments and the skilful use of the gloved fingers.

Cancer of the fundus of the uterus is usually an adenocarcinoma and in the early stages the diagnosis depends in a great measure upon the microscope.

The prognosis in these cases is much more favorable than those of the cervix, perhaps 75 per cent. of operations performed early resulting in cure with freedom from recurrence. Such results are due to the slowness with which lymphatic metastasis occurs and to the position of the growth, far removed from the vagina, bladder and rectum. Lubarsch offers the explanation that in cancer of the uterus the epithelial cells are quite large and cannot easily enter the lymph radicles.

Cancer of the body of the uterus requires complete hysterectomy and in the early stages may be removed through the vagina.

The Hemoglobin and Corpuscular Content of the Blood of the Newborn.—It has been found by A. O M. FEHRSEN (Jour. of Physiol., Dec. 14, 1903) that the blood of the infant at term contains a high percentage of hemoglobin, 110 to 115 per cent.; shows a large increase in the erythrocytes with a mean of 6,047,000 per cm.; a well-marked leucocytosis, 18,000 per cm., and an absolute and relative increase in the lymphocytes.

THE OCCURRENCE OF TÆNIA NANA IN TEXAS (THE FIRST, OR, AT LEAST, THE SECOND, REPORTED CASE IN NORTH AMERICA).*†

BY JOHN T. MOORE, M.D.,
OF GALVESTON, TEXAS;
ASSOCIATE IN CLINICAL MEDICINE, UNIVERSITY OF TEXAS, MEDICAL DEPARTMENT; AND SURGEON G. H. & H. RY., GALVESTON.

I TAKE this opportunity of presenting to this Association a case that is of rare occurrence in this country.

On Aug. 2, 1902, a section foreman, who works for the Galveston, Houston and Henderson Railway, consulted me for a severe diarrhea, great weakness, and cramps in the abdomen. He was given a diarrhea mixture and asked to return in case he was not relieved. He came back on August 4, stating that he was no better. I suspected from the history that he was suffering from amebic dysentery or some intestinal worm and asked him to go to the infirmary where he could receive the proper care and have the stools examined. I gave instructions to save all the stools passed and to examine carefully for all intestinal parasites and their ova.

Dr. J. R. Elliott, interne at St. Mary's Infirmary, to whom is due the credit of first finding the ova, reported that he had found the ova of some tapeworm that he thought fit the description of *Tænia nana*. We went over the examination very carefully together and soon became convinced that we had the ova of *Tænia nana*. I ordered an anthelmintic given and instructed them to save everything passed. Much time was spent in washing the stool through a muslin cloth, but without finding anything. I now adopted the plan of putting small quantities of the fecal material in a clear glass beaker filled with water. We were soon rewarded by finding pieces of the worm. We washed quite a good deal of the material, hoping to find the whole worm, or at least the head, but were unsuccessful.

Fig. 1.

Hymenolepis nana (x 18) (Leuckart).

I submitted specimens to Dr. C. W. Stiles, chief of the Division of Zoology, Washington, and Dr. A. J. Smith, Professor of Pathology, University of Texas, for identification. They very promptly verified our diagnosis of *Hymenolepis* (*Tænia nana*), as shown by their notes, which I here publish.

Washington, D. C., Aug. 28, 1902.

Referring again to your letter of Aug. 9, I would state that the specimens have been stained and mounted. Unfortunately, the material is in a poor state of preservation, so that it was impossible to make any very minute observations upon it. Nevertheless, sufficient

*A preliminary note on *Tenia nana* in Texas was published in the University of Texas Medical, April, 1903.

†Read before the State Medical Association, April, 1903, San Antonio, Texas.

was seen to lead me to believe that you are safe in classifying the tapeworm as *Tenia nana*, or, according to the more modern classification of tapeworm, as *Hymenolepis nana* (Siebold, 1852).

C. W. Stiles.

Galveston, Texas, Sept. 10, 1902.

The specimen of tapeworm links sent me to-day, with request to confirm or correct your identification as *Tænia nana*, has been examined.

I am confident of the correctness of your diagnosis. The specimen is extremely rare, and its occurrence here should be reported for record. Very sincerely,

Allen J. Smith.

Case.—T. O'C., section foreman in G., H. & H. yards. Residence, Galveston; single; age thirty-five years; born in Ireland. Family history.—Father died at age of sixty-eight years; mother died at about the same age. Previous health of both parents good. Four brothers and four sisters living and in good health. Personal history.—Drinks beer and gets drunk now and then. Smokes tobacco. Previous residence.—Came from

Head of *Hymenolepis nana*, with retracted rostellum (x 100) (Leuckart).

Ireland to Sedalia, Mo., in 1879, passing through Boston. He lived at Sedalia eighteen months, working on the railroad tracks and in the yards there. From Sedalia he came to Texas, stopping first at Laredo, thence to Waco, Dallas, Longview, Palestine and San Antonio. He worked at Cleburne, Texas, four or five months during 1882, and at Houston most of 1883. From 1883 to 1891 he was working at Galveston or in that vicinity. In 1892 he worked on the Galveston jetties. He worked on the Santa Fe Railway, near Arcola, Texas, during 1893. In 1894 he was working on the Alta Loma pipe line, the line furnishing Galveston her water supply from artesian wells 18 miles away. Worked on City Railroad during 1895; after this he went to Houston for three years, thence back to Galveston in 1900 where he has since lived. During all of this time he says that his health was perfect. Previous diseases none. Present disease.—Two months before entering hospital, which was on Aug. 4, 1902, he felt feverish, especially during the mornings and had considerable headache at times. He would be well for two or three days and then get sick again. Appetite was good and bowels regular during this time. One week before consulting me (July 28, 1902), he was taken with a severe diarrhea. The bowels would move eight or ten times during the day and as often during the night. There was considerable pain in the belly about the umbilicus. He passed much blood and mucus; appetite poor. He complains now, Aug. 3, of pain in belly, diarrhea, and great weakness. Present condition.—He is a tall man, height 6 feet, weight about 150 pounds, rather sparely built, temperature 101° F., pulse 110, respiration 18. Heart and lungs normal. Liver and spleen a little enlarged. Some tenderness over stomach and abdomen. Some intestinal parasite was suspected and he was advised to enter the hospital, which he did Aug. 4, 1902. The blood examination for malarial parasites was negative. Aug. 5.—The patient passed a very restless night. The bowels moved about 20 times during the past twenty-four hours. The stools were examined by Dr. J. R. Elliott who reported finding the ova of some intestinal worm, probably *Tænia nana*. I ordered the following given:

℞ Olei resin Aspidii.....1 dram
Ext. Kamalæ Fld.....1 dram
Ext. of Krameriæ Fld.....½ dram

To be taken at 9 A.M., and followed by one ounce of castor oil.

Aug. 8, temperature normal and patient feeling well. He insists upon going out. March 22, 1903, I saw the patient to-day and he says that his health is fine. He has not been sick since leaving the hospital.

Historical.—The parasite was discovered by Bilharz in 1851 in the intestine of a young man who died of meningitis. The worm was found in great numbers. A description was given by Von Siebold and Bilharz a little later. Leuckhart, afterward gave a complete description from specimens given him by Bilharz. Four specimens of this tænia are found in the collection of worms in the College of the Faculty of Medicine, in Paris. They had been given to Dr. Davaine by Burguieres.

Hellich in 1885 obtained some of these worms in a child seven years old. This was the daughter of a barber. She was given male fern and passed a *Tænia solium*, a few *Oxyuris vermicularis*, and about 50 *Tænia nana*. Other doses of this drug were given and in five successive times she passed 250 of the worms. Leuckhart received some of these specimens and identified them as *Tænia nana*.

There are specimens to be found in the museum of Orfila said to have been given by Prof. Dokitch in Sept., 1885, secured while traveling in Servia.

In 1873 Spooner found a small worm in the United States which he thought to be *Tænia nana*. The specimens were given to the College of Physicians of Philadelphia. Leuckhart is disposed to think the specimen was *Tænia flavopunctata*. If this was *Tænia nana* then it was the first case occurring in North America.

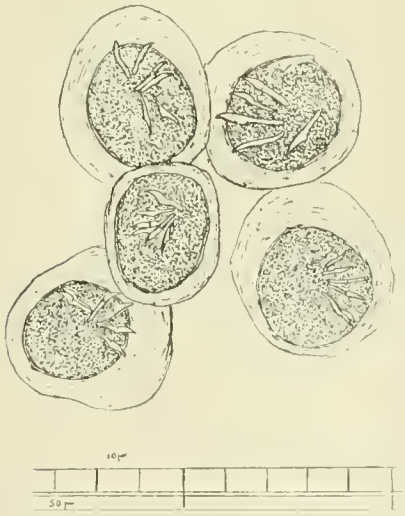
Geographical Distribution.—This tænia has been found in many parts of the world. Bilharz discovered the parasite in Cairo, Dr. Haley found the worm in a seven-year-old child in Belgrade.

Specimens were obtained from Servia in 1885. Spooner thinks he found the tænia in the United States at Philadelphia. Grassi says this is a very common parasite in Sicily. He secured specimens of the worm from two Sicilians. Ransom observed *Tænia nana* in England. It is known to exist in Lombardy (Grassi, Comini, etc.); Piedmont (Peroncito), Tuscany (Sonsino), and Sicily (Grassi and Calandruccio). Grassi found it in Marseilles, Zograph found it in Russia and Mortens in Germany. Lutz found it in two little girls in Brazil. Wernicke and Blanchard found the worm in the Argentine Republic.

My case evidently contracted the parasite here in the vicinity of Galveston. There were two men, working on the section with this man, who had diarrhea of the same character, but I was unable to secure feces for examination. I feel convinced, since finding *Tænia nana* in this man, that the other two were also infected.

Dr. Stiles writes me that he has recently found four cases in Georgia and one of his assistants has found another case in an asylum in Washington.

Fig. 3.



Ova of *Tænia nana* (from crushed ripe segment). Drawn by Dr. A. J. Smith (camera lucida).

The parasite is evidently much more widely distributed than we have heretofore thought.

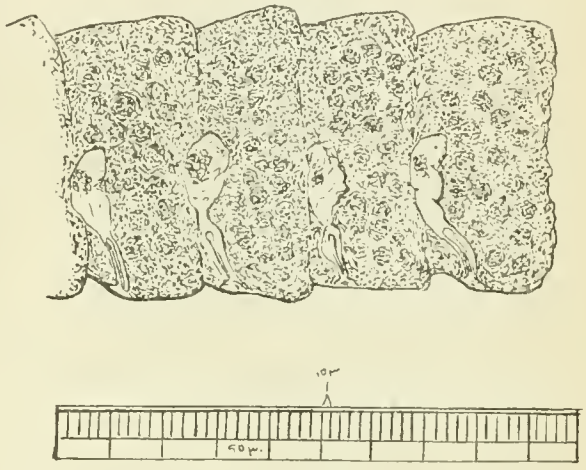
Generic and Specific Diagnoses.—Genus—*Hymenolepis* Weinland, 1858.

Generic Diagnosis—Dipylidiinæ: body small, filiform; head small, rostellum retractile, well developed and armed with a crown of 24 to 30 small hooklets; or rudimentary and unarmed; suckers usually unarmed. Neck long; lateral border of strobila has serrate appearance much like the toothed edge of a saw blade. Genital pore single, unilateral, on left margin. Testicles usually three to each segment, two on right, one on left side. Gravid segments transformed into a sac full of clear, round, or oblong eggs which are surrounded by three shells; internal shell occasionally with a small knoblike structure at each pole. Larva a cryptocyst or a staphylocyst.

Type Species.—Tænia flavopunctata (Hymenolepis diminuta).

Synonyms.—Hymenolepis Weinland, 1858; *Diplocanthus* Weinland, 1858 (not Agassiz, 18, fish); *Lepidotrias* Weinland, 1858; *Diplocanthus* Cohn, 1899 (misprint).

Fig. 4.



Segments of *Tænia nana*. Drawn by Dr. A. J. Smith (camera lucida).

For list of species and bibliography see Blanchard, 1891, Hist. zool. et med. des T'eniad 'es du genre *Hymenolepis,* Paris, 112 pp., 22 figs.

The Dwarf Tapeworm—Hymenolepis nana (Siebold, 1852; Blanchard, 1891).

Specific Diagnosis.—Hymenolepis strobila attains 10 to 40 mm. in length, and 0.5 to 0.9 mm. in breadth; composed of about 150 to 200 segments. Head subspherical, 0.25 to 0.33 mm. in diameter; rostellum thick retractile, 100 μ long, 80 to 90 μ broad; hooks 20 to 30 in number, 14 to 18 μ long, and arranged in a single row; suckers lobular, 90 to 105 μ (according to some authors to 200 μ) in diameter. Unsegmented neck quite long, not distinctly defined from head and about half as broad. Anterior proglottids very short, scarcely distinct; those following become gradually longer and broader, always remaining broader than long, attaining 0.14 to 0.30 mm. in length, by 0.41 to 0.92 mm. in breadth. Vitellogene gland globular. Only about 100 eggs found in gravid segments; eggs globular to oval; outer envelope 30 to 60 μ; inner envelope 16 to 28 μ, presenting at each pole a more or less conspicuous mammillate projection provided with filamentous appendages; onchosphere 16 to 22 μ by 18 to 20 μ in diameter; hooks of onchosphere 10 to 14 μ long.

Synonyms.—*Tænia nana* von Siebold, 1852 (not P. J. van Benden, 1861); *Tænia Ægyptiaca* Billharz, 1852; *Diplacanthus nanus* Weinland, 1858; *Tænia (Hymenolepis) nana* Leuckart, 1863; *Tænia murina* Dujardin (not Gmelin, 1789).

Description of Specimens.—Fig. 4 shows four segments in which it is seen that the genital opening is on the same side as the segments. These segments are almost far enough toward the tail

Fig. 5.

Egg of *Hymenolepis nana*, drawn by Brayton H. Ransom, Division of Zoology, Hygienic Laboratory, U. S. Public Health and Marine-Hospital Service.

end to contain mature ova, as one is seen at *a*. Owing to the specimens being in a poor state of preservation no minute observations could be made, but one can make out the remnants of the male genital organs which are seen in the drawing. The immature ova have filled the uterus and make it conform to the shape of the segments.

The Ova.—The mature segments which contain from 20 to 30 ova were carefully studied. When the ova are first encountered Fig. 3 gives a good idea of their appearance, the hooklets of the embryos being seen without any difficulty at all. The interval between the outer and inner shells is seen upon very close observation to be made up of a substance which is quite clear, but running through it and apparently coming from what may be termed the poles are a number of filaments. These are made out with great difficulty. Fig. 5 shows this quite well. Lying within the inner shell is the embryo which has six hooklets in most cases, but quite a number of ova were seen

Fig. 6.

Egg of *Hymenolepis nana* (38 x 31μ) (original).

having only five due probably to their being obscured by the others. The average for a number of measurements was: outer shell 40 by 31.9 μ; the inner shell 29.2 by 20.6 μ. The hooklets which are shown in the ova measured from 10 to 13μ in length. Fig. 7 shows a hooklet enlarged.

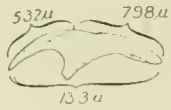
Pathological Significance.—It is not known definitely how the infection is gotten, but from the great number found in the intestines it has been suggested that the ova are taken into the stomach with water or vegetables. It is not my aim to discuss this phase of the subject here but it is quite desirable that some one discover the means of infection. This parasite has been found in large numbers in the small intestine and they have been known to pass through the ileocecal valve. Thousands of these worms may inhabit a single intestine.

The symptoms may be divided into two main groups: (1) Intestinal; (2) nervous.

1. *Intestinal.*—From the irritation of the mucous membrane of the intestine there is apt to be loss of appetite, diarrhea, alternating with constipation, colicky pains in the abdomen and stomach, and great nausea.

2. *Nervous.*—The *nervous symptoms* are headache, disturbance of vision, dizziness, melancholia and in many cases attacks of epilepsy. Where only a few parasites are present there may be no symptoms at all, but if the worms are numerous the symptoms are apt to be of a severe character. Anemia follows later with its train of symptoms. One is somewhat at a loss to account for such severe symptoms where so few worms are present, but, as they rapidly disappear upon ridding the patient of the worms, the parasite must be responsible for them. They must be caused by

Fig. 7.



Hook from embryo (enlarged) (original).

the combined irritation to the intestine and the liberation of toxines. The predominant symptoms in my case were obstinate diarrhea, cramps in the abdomen and limbs, headache, and great weakness. One dose of the anthelmintic completely relieved him.

Diagnosis.—The diagnosis is readily made by examination of the stools microscopically. The ova are easily recognized.

Treatment.—Male fern is the best drug to use for their expulsion. One dram of the oleoresin of male fern, taken after a fast, and followed by an active purge is usually all that is needed. Thymol and santonin are said to be of no value.

I am very much indebted to Dr. Charles W. Stiles, chief of Division of Zoology, for his identification of the parasite and for the generic and specific diagnosis and for his aid in the study of the ova and the segments; and to Dr. A. J. Smith for his assistance in the preparation of drawings and his assistance in many ways. Also to Mr. B. H. Ransom, Washington City, for his excellent drawing of the egg.

TWO ADVANTAGEOUS PROCEDURES IN ANESTHESIA WORK: REPORT OF CASES.

BY VICTOR C. PEDERSEN, A.M., M.D.,
OF NEW YORK.

IN presenting the following two procedures in anesthesia work, no claim to originality is made, excepting such as may be concerned in the facts that the author never has seen them described before and never has seen them employed previously, but had to work them out for himself in the course of active experience as a specialist in anesthesia. They are published only with the hope that some one who has not learned of them before may profit by them.

The first procedure is an advantageous means of administration of the nitrous oxide-ether sequence. Strictly speaking, it is a new sequence in which the series is nitrous oxide, then nitrous oxide and ether combined and finally ether alone. The purposes of the technic are to avoid producing any gas cyanosis, to induce ether narcosis very slowly without exciting any reflexes, such as coughing, and finally to obtain a full degree of ether narcosis with the utmost safety and convenience to the patient.

A fourth result, which is incidental rather than essential, is great economy of gas, since by this method the average patient goes completely under this sequence of these anesthetics with a half-gallon instead of a full gallon of gas.

The details of applying the technic are as follows, so far as the Bennett apparatus, which is the one I prefer, is concerned. Exactly similar stages of the procedure are possible with any of the other good ether-cones now on the market.

First.—The gas-bag is filled to its half-capacity for the average patient, or to a fuller degree if there be any reason to suspect necessity for using a larger quantity. The ether chamber is as usual charged with ether, from a half-ounce to a full ounce in quantity, likewise in accordance with the characteristics of the patient. The assembled cone is now placed upon the patient's face and the rubber face-cushion is adjusted to fit as well as possible. With the valves of the gas-chamber open, the patient is requested to breathe; and as soon as he has shown himself to understand what is required of him, and the face-piece has been seen to fit air-tight, the gas is turned on.

Second.—After from two to four full respirations have been taken with the expiration-valve of the gas-chamber open, this is closed so that "rebreathing" is therefore initiated.

Third.—The patient is now allowed to take from two to four respirations in this manner, at the end of which he is usually sufficiently under gas-narcosis for the next step, although as a rule not in the smallest degree cyanosed by the gas.

Fourth.—This step consists in very slowly turning on the ether, at a rate so deliberate that it requires from four to eight minutes to pass from *"air"* to full *"ether." During this stage it will be noticed the patient is receiving nitrous oxide and ether together thus constituting the second anesthetic combination of the sequence already outlined.*

Fifth.—While this combination is being administered the quantity of ether in the ether-chamber is judiciously replenished and, if necessary, likewise increased, so that usually at the end of the time stated the patient has begun full, regular and stertorous ether-respiration. This degree of narcosis is commonly reached without any reflexes or disturbances whatever. *Cyanosis if it appears at all, is not of the blue-gray hue of gas-, but of the reddish-blue image of ether cyanosis.*

Sixth.—If there is any delay in the appearance of the normal ether respiration, I continue the nitrous oxide ether combination of the series until it does develop. The additional time required, in such cases, for the induction of full ether-narcosis is usually very brief.

Seventh.—When all the symptoms of complete ether-anesthesia are present, the gas-chamber and bag are removed and the ether-bag is attached to the ether-chamber and the patient is ready for operation.

Comments and Results in Practice.—I have now had perhaps 150 patients in private and in public practice in my official position at the Roosevelt and at Polyclinic hospitals, whom I have anesthetized in precisely this manner. Of these 150 only one has shown the usual *gas-cyanosis* in more than a very moderate degree, but he was alcoholic and took the anesthetic only fairly well throughout, showing, as most of these subjects do, great readiness to become cyanotic under any anesthetic.

I have likewise had only two or three patients who coughed at all during the introduction of the ether. Only one patient was able, after convalescence, to tell me that she perceived the odor of the ether, of which I have great doubts, founded on her behavior in going under. Since applying this method, the majority of my patients have had very much less mucus in the nose, throat and trachea and the majority of them have shown distinctly less after vomiting. The benefits of this mode of administration lie in the fact that the induction of the ether narcosis is much more deliberate, regular and steady and that, therefore, the concentration of the fumes is more carefully determined with reference to each patient's peculiarity; which is an exceedingly important detail.

When I was taught as a hospital interne, the gas-ether sequence of anesthesia, the method practised was to induce profound gas-anesthesia to the point of distinct cyanosis and then to turn on the ether more or less rapidly before the patient had time to recover from the gas. The result was a great advance over the old mode, but still had the objection of very frequently causing coughing, bronchorrhea and ether-excitement, including considerable muscular resistance simply because the ether was necessarily concentrated. Of my series of cases, very few indeed

have shown muscular resistance; and such as have, did so to a very insignificant degree, with the exception of one very alcoholic subject (the same individual just spoken of as having shown more or less gas-cyanosis).

"I feel that in presenting this rather simple and sensible procedure to those who are working in the field of anesthesia, I have offered a very valuable suggestion, since the experience I have had with it seems to be a criterion.

Reports of Cases.—It seems well to outline several cases, which illustrate the satisfactory manner in which this technic operates in actual practice. These histories are copies of notes kept of many of my cases. The reports of the postoperative conditions were very kindly made by the nurses, at the permission of the operating surgeons in great courtesy, which is sincerely appreciated, or by the operators themselves.

Case I. D.—*History*: Male; white; seventy-five years old; retired merchant; no previous anesthesia; no stigmata of alcoholism; about five feet eight inches tall; weight, 110 pounds; of fair development for his age; of poor nutrition; of pale complexion and in feeble general health.

Physical Examination Prior to the Anesthesia.—(1) *Circulatory System:* Small intermittent pulse, 80 beats to the minute; general arteriosclerosis; veins negative; considerable pallor and anemia. (2) *Respiratory System:* Atrophic senile rhinitis; chronic nasopharyngitis; lungs normal to auscultation in front and on the sides, age considered; breath-sounds slightly puerile; expiration prolonged; no cough; stomach empty; rectum loaded; urine not reported; no ante-operative drugs; slight fear.

Pathological Condition.—Obliterating endarteritis with secondary gangrene of one toe. *Operator*, Dr. John A. Bodine. *Operation.*—Amputation of the toe; duration, twelve minutes: Bennett inhaler, using a half-gallon of gas with $1\frac{1}{2}$ ounces of ether net, measured; no anesthesia excitement; dorsal posture; complete relaxation; no mucus; very slight sweating; no laryngeal spasm; moderate exposure during operation; no shock; slightest hemorrhage. *Recovery.*—No after-vomiting; within eight minutes conjunctivæ sensible and conscious within thirty minutes so as to speak; no postoperative stimulants.

During the anesthesia his pulse varied between 80 and 90 and was of better character than previously. His respiration was 36 and normal; his conjunctival reflex disappeared completely. The reflex of his pupil to light was constantly present and the size of the pupil was moderate in a room of only fair illumination. No movements whatever were made excepting a few swallows early in the anesthesia. His color was better during the anesthesia than either before or after. His general condition remained excellent.

The *technic* already described was followed exactly in inducing the anesthesia; only two respirations were allowed with the expiration-valve of the gas-chamber open, and only two more with it closed, after which the ether was begun. Within four minutes from the beginning the conjunctival reflex was sluggish and stertor was appearing. In two minutes after this time the operation was begun.

The nurse at the permission of the operator, reported the next day by letter, that the first twenty-four hours passed without incident and that during this time he had passed his urine voluntarily. No examination of the urine postoperatively was reported.

Case II. S.—*History:* Male; white; forty-five years old; merchant; no previous anesthesia; moderate regular alcoholic habit; five feet six inches tall; weight, 210 pounds; of excellent muscular development, nutrition and general health; complexion ruddy.

Physical Examination.—Entirely negative excepting the urine which contained blood, pus and a trace of albumin due to the blood; slight cystitis; no anteoperative drugs; no fear. *Operator*, Dr. E. L. Keyes. *Operation.*—Lithotripsy; duration twenty-five minutes; Bennett inhaler; two-thirds of a gallon of gas and $5\frac{1}{8}$ ounces of ether were used; no anesthetic excitement; dorsal posture; complete relaxation; moderate mucus; very great sweating; no laryngeal spasm; very moderate hemorrhage, gentle operative manipulation; no exposure during operation; no shock; no postoperative stimulants.

During the operation his pulse remained constant at 84; his respiration varied from 30 to 36; his conjunctival reflex was abolished. The reaction of the pupil to light was active and the size of the pupil small in a very brightly illuminated room. He moved very slightly early in the operation when the instrument was first introduced, but was quieted by increasing the quantity of ether. His color was bluish for a time, due to swelling of the tongue and was corrected by pulling the tongue forward with the forceps. No gas-cyanosis occurred. No excitement in going under of any description.

Recovery.—In three minutes his conjunctival reflex was present and in six minutes he vomited once; he vomited again on the way to his room, and once after arrival there. The nurse reported by postal three days afterward that his recovery from the anesthetic was perfect. The quantity of ether used was due to the facts of his alcoholic habits in his club-life, of his great physical size and of the amount of air necessary through the upper valve in order to keep his color good Urine normal in a few days.

Case III. G.—*History:* Female; white; twenty-seven years old; housewife; previous anesthesia, none; moderate regular alcoholic habit; five feet six inches tall; heavy build; weight, 185 pounds; excellent development, nutrition and general health; ruddy complexion.

Physical examination prior to operation negative; no drugs given; very moderate fear. *Operator*, Dr. J. D. Nagel. *Operation.*—Curetting, dilatation and incision of the internal os uteri for sterility, secondary to stenosis; duration, sixteen

minutes; Bennett inhaler; a half-gallon of gas and 2¾ ounces of ether, measured; dorsal lithotomy posture; absolute relaxation; very moderate mucus; moderate sweating; usual exposure during the operation. Three respirations were allowed with the expiration-valve open, which was then closed and the ether introduced. After a few respirations roars of true laughter set in, due to the gas, but not associated with any gas-cyanosis whatever, which lasted until the ether stertor appeared; that is, about two minutes. During the laughter the patient shook her whole body, especially the limbs, but was not muscularly rigid, nor at all combative; no restraint. Deep anesthesia was present in about three and one-half minutes and was accompanied by very moderate cyanosis which disappeared as soon as the upper air-valve was opened. It had none of the gray-blue characters of gas-cyanosis. The upper air-valve was kept open and no further cyanosis appeared. Some laryngeal spasm in the form of inspiratory stridor was present during the first few minutes but rapidly disappeared.

During the operation the behavior of the patient was entirely without incident. After removal of the cone hiccoughs began within two minutes and vomiting associated with hysterical weeping in six minutes. The nurse reported by letter in about a week that after returning to the ward little or no vomiting appeared and that recovery from the anesthesia was complete and uneventful. No report of the postoperative urine. During the operation the patient's respiration reached 50 to the minute varying between that and 36. Pulse normal at about 100. There was no postoperative medication required.

Case IV. S. L. F.—*History:* Male; white; forty-five years old; merchant by occupation; no previous general anesthesia; very pronounced alcoholic habit, consuming a quart of whisky and other forms of alcohol in addition each day at the time of operation, as acknowledged by his wife.

Physical Examination.—Five feet six inches; medium build; poor development and nutrition, pale complexion with marked jaundice; heart, lungs and kidneys pronounced healthy by family physician, who requested me not to investigate them less the patient's irritable disposition be excited. General arteriosclerosis; no cough; stomach and rectum empty. No drugs immediately before operation.

Pathological Condition.—Atrophic cirrhosis of the liver with secondary ascites of very marked degree. Two days prior to the operation, twenty-five pounds of fluid were aspirated. On the day of the operation the abdomen was enormously distended and tense. *Operator:* Dr. R. T. Morris. *Operation:* Talma's procedure to establish anastomotic circulation between the liver and omentum and the wall of the abdomen. Bennett's inhaler; 6¾ ounces of ether (measured), preceded by one gallon of gas during a total administration of thirty-eight minutes; dorsal posture; absolute relaxation. Slight mucus; very moderate hemorrhage in the wound; profuse sweating; rapid general manipulation; moderate exposure during the work. No laryngeal spasm. *Recovery:* in ten minutes conjunctival reflex had returned and in one hour the patient was thoroughly conscious and able to converse rationally. About one week after the operation Dr. Morris informed me that his recovery up to that moment had been without incident. There was very little after-vomiting and only a very mild degree of shock. No postoperative stimulants.

The *anesthesia* was exceedingly interesting. Realizing that I was dealing with a very undesirable case, I took a gallon of gas, allowing the patient to expire half of it before compelling rebreathing. The ether was then very slowly turned in so that I consumed ten minutes in getting the patient under. There was no struggling whatever and no reflexes, cyanosis or other undesirable features until without warning about twelve minutes after the first gas was administered the patient's nose and throat suddenly filled with blood and mucus and deep cyanosis suddenly appeared. Breathing stopped absolutely and I thought the patient was dead of cardiac failure. During the month preceding the operation he had had at least two slight marked epistaxes. The cause of his suspended breathing appeared to be a sudden filling of the upper air passages with blood and mucus, probably from this source. I immediately opened his mouth with a gag, drew his tongue forward, swabbed out the passage and summoned Dr. Morris to the room, requesting him to institute artificial respiration while I kept the upper air passages free. I explored the larynx with my finger and was pleased to find that it was clear. Perhaps a half dozen manipulations in artificial respiration were made when the patient began to breathe again. After a few minutes his breathing was normal and the anesthetic was resumed with the mouth gag in place and the tongue pulled forward. At the end of the eighteen minutes from the outset the operation was begun and as soon as the fluid from the abdomen was evacuated his pulse, which had been 108, suddenly rose to 160. His respiration again became faulty and another epistaxis occurred, more moderate, however, than the first. It required only a swabbing out of the throat to clear the difficulty away. In a minute or two the pulse and respiration improved markedly so that they were much better than at any previous moment, and thus they continued until the end of the operation. In fact, the great improvement in this patient's condition suggested to both Dr. Morris and to myself, the advisability of evacuating the abdomen of ascitic fluid a few hours before beginning the anesthetic.

This case is mentioned to show how this new method of administering gas and ether will work even with individuals who otherwise would

present a high degree of furious excitement while going under. All things considered, his performance under the anesthetic was as good as could possibly be expected. Certainly the beginning of the narcosis was as free from trouble as possible, aside from the obstruction of his breathing with mucus and blood, which in all human likelihood depended more upon his disease and the general interference with circulation and respiration it caused than upon anything else.

The quantity of ether required, 6¾ ounces in thirty-eight minutes in administration, was really very small indeed, when one considers the quantity of alcohol in various forms the patient was consuming each day. The only ether excitement he showed was during the first twenty minutes of the recovery when he was in a state of talkativeness and profanity, but at the end of an hour was quite himself again.

The second valuable procedure in anesthesia work implied in the title, is that of the *new position of the patient for operations upon the kidney*. The usual manner of placing these patients upon an Edebohls' bag involves the crowding of the root of the neck and face more or less closely against the top of the table. I have seen cases in which this was present in so marked a degree, that it was impossible to move the head of the subject about, excepting with both hands and force enough to practically life the shoulders from the table. I have also seen the pressure so severe that the lower jaw was held rigid and pushed considerably out of its position toward the opposite side of the face.

I am convinced that such interference with the patients' air-passages accounts far more for the bad manner in which they take the anesthetic than does the anesthetic or the surgical operation itself.

One of the fundamental principles of good anesthesia work is that the head and neck of the patient shall be as fully under the control of the anesthetist as possible. The position of these kidney cases, as just outlined, totally deprives the anesthetist of this most important aid in securing a satisfactory anesthesia. It was with the purpose of correcting the difficulty that I have come upon and now invariably adopt the following very simple plan. I have had, since it first occurred to my mind, a sufficient number of cases to prove absolutely that it works perfectly and is the proper solution of the difficulty.

The steps of the method are simply these. After the patient is suitably narcotized in the dorsal position, he is transferred to the operating table, turned upon his side, and the Edebohls' bag is placed into its position. The shoulders are then raised from the table and rested upon a sand-bag reaching from shoulder to shoulder, oval in cross section, about four inches in its longest diameter and reasonably soft. This brings the pressure of the chest upon the shoulders and upper sternum, and not, as heretofore, upon the base of the neck. When the shoulders are thus elevated free of the table the head may be moved in any direction whatever and the jaw of the patient is absolutely under the control of the anesthetist.

The technic has one objection which may, however, be readily corrected, as I will presently state. It is that the elevation of the upper part of the chest upon the sand-bag may narrow the iliocostal space and thus decrease the field of operation. My method of meeting this difficulty, is to place other sand-bags under the Edebohls' bag, thus securing a proper flexion and torsion of the chest upon the abdomen. Of the series of cases to which I have applied this technic all have followed an uneventful anesthesia with a sole exception which should not properly be mentioned with a description of the technic because I feel there is no relation between them. In this example the surgeon did not follow my suggestion to elevate the Edebohls' bag upon other sand-bags and therefore operated in a slightly restricted iliocostal space. It was on this account that in delivering the kidney his manipulations were so severe that not only did he contuse the organ somewhat but also brought about a reflex suspension of respiration which occurred in the presence of a perfectly good color and no circulatory symptoms aside from slight acceleration of the pulse. The operation was suspended, and in a moment or two without any interference whatever with the patient, respiration was resumed.

When one considers that kidney-operations are perhaps among the most dangerous attempted and that it frequently matters very little what anesthetic is employed, because any is apt to be followed by some kidney-disturbance in virtue of the other attack upon these organs, it becomes of supreme importance to so place the patient that all possible disadvantages of the anesthetist are removed.

In my experience I have proved to my entire satisfaction that this arrangement of the patient suits the elements of the proposition perfectly. Its importance lies in the fact that one never may state in advance how a given patient will accept a certain anesthetic during the operation and during the convalescence. Some authorities state that chloroform is better than ether for renal subjects, while others, on the contrary, say that while ether very frequently irritates the kidneys the character of its disturbance is usually functional, immaterial and temporary. Chloroform by these authorities is perhaps with great truth stated to be exceedingly deadly whenever it meets a kidney susceptible to it in that its effect is profound and almost organic.

I feel therefore that too much stress cannot be laid on the importance of securing freedom of the head and neck as a most important aid to the narcotizer in giving either of these anesthetics or any other anesthetic as uneventfully as the idiosyncrasy of his patient will permit.

16 West Sixty-first Street.

LABORATORY AIDS TO DIAGNOSIS FOR THE GENERAL PRACTITIONER.*

BY VICTOR A. ROBERTSON, M.D.,
OF BROOKLYN, N. Y.

To-day the medical profession, as well as humanity at large, is greatly indebted to the many achievements and triumphs of the modern well equipped and scientific laboratory.

Anatomical laboratories for teaching and investigation have existed almost from the beginning of medical progress, but the clinical laboratory of the present time is a product of only the last thirty years. As a factor in medical education its value can hardly be overestimated. Cases of disease are now studied with the aid of the microscopist and the bacteriologist as well as the clinician. Anatomical and hygienic laboratories deal frequently with problems having no direct bearing on the practical side of medicine, but the clinical laboratory brings us in close touch with the patient and pathological materials derived from living subjects.

It is only within recent years that opportunities have been given in our medical schools, for original investigation in morbid processes, and many of our older practitioners can remember the times when advantages for such research could only be had abroad, the birthplace of these laboratories. Now their usefulness being recognized, every well-equipped medical school is provided with its clinical, physiological and chemical laboratories. There can be no dispute as to the profound influence exerted upon practical medicine in diagnosis and treatment by laboratory methods of investigation. These methods are not to be used to the exclusion of the physical examination, history, temperature, pulse, etc., but as affording a valuable means of adding to our information in any given case, and must always be taken in conjunction with all the bedside methods of diagnosis of the clinician. We must not relax in physical methods of diagnosis or fail to remain acute observers of all the objective signs of disease, and give all the findings in any given case due consideration. These aids to precision in diagnosis have been neglected to a large extent by the general practitioner, except to those who are fortunate enough to be hospital visitants.

This neglect has been due, in some cases, to indifference or disbelief as to the practical value of these methods, in others to a mistaken idea that a large amount of technical skill is required, that much time is necessary, and expensive apparatus is essential.

It is the purpose of this paper to encourage the general practitioner to conduct these examinations himself and he will soon appreciate their immense assistance in his professional work. Every practitioner is morally bound to use every means at his disposal to arrive at exactitude and completeness in diagnosis and no man should be too busy to make daily examinations of blood, sputum, urine, gastric juice, etc. If professional duties prevent, he should avail himself of the services of an assistant qualified in laboratory methods. If the clinician could combine with his experience, mature judgment and skill in physical examination, a knowledge of laboratory technic, diagnostic errors would occur less frequently and much less discredit would be placed at the door of the laboratory diagnostician. Many unjust criticisms have been made of laboratory diagnoses, because the clinician, through his ignorance of laboratory methods has sent his material for examination contaminated to such a degree that no successful investigation could be made, or the data furnished has been insufficient. It must be understood that the microscope only reveals evidence that is complementary to the physical signs and symptoms. It is only one factor that must be correlated with other sources of information before a definite conclusion can be reached.

The general practitioner should remember that scientific completeness is not required of him in this work. It goes of course, without saying, that the intricate details of original research are too engrossing and demand more time and technical skill than a busy practitioner can afford. It does not require, however, but a moderate knowledge of bacteriological methods to discover the commoner pathogenic organisms that he meets with in diseased processes almost daily.

A laboratory could be fitted up at moderate expense in a room separate from the office, where the necessary quietness could be obtained, a hall room, provided with water and gas, would answer admirably. The most expensive part of the equipment would be a good microscope with ⅔″ and ⅙″ dry lenses and $^1/_{12}$″ oil immersion lens, and mechanical stage. A table and some shelves and racks for holding the necessary glassware, chemical reagents and staining solutions which could be modest at first and added to from time to time as occasion required. An Esbach albuminometer, a Doremus ureometer, Einhorn's saccharometer, A Thoma-Zeiss hematocytometer, Dare's hemaglobinometer or Tallquist's hemoglobin scale are necessaries. An incubator, while not perhaps an essential part of the equipment at first, would soon be willingly obtained by an enthusiastic worker. An hour or two spent daily in this laboratory would be an agreeable relaxation from engrossing professional duties.

Some time ago an article appeared in one of our leading medical journals, written by Dr. E. L. Trudeau,* of Saranac Lake, in which he narrated the great difficulties he encountered in laboratory work in his early professional days in the Adirondacks. One can only admire his persistency in adhering to scientific methods of diagnosis in the face of the discouraging and limited facilities at his command in that rigorous climate. His efforts have been crowned with deserved success, as may be seen in the admirably equipped and well-organized laboratory that bears his name in Saranac Lake, N. Y.

* Read at the Annual Meeting of the New York State Medical Association, October 21, 1903.

* See MEDICAL NEWS, Oct. 24, 1903.

In this city we have at hand, at convenient stations, a suitable culture medium for all the commoner pathogenic organisms. The writer refers to the Löffler blood serum mixture, in test tubes, furnished by the Health Board. These can be carried to the bedside, hospital, dispensary and autopsy table for inoculation.

The applicability of these methods in daily practice may be shown by the following: A case of continued fever with ill-defined symptoms presents itself for diagnosis.

Osler states that all fevers extending over several days in this latitude are apt to be one of three things, tuberculosis, typhoid fever or malaria. If cough is present and a specimen of the sputa can be obtained, it is only a matter of a few moments to pick up one of the small cheesy masses met with if the sputum is tuberculous, make a smear, fix it by flaming, stain, decolorize, use contrast stain, dry, and examine, and tubercle bacilli, if found, will make the diagnosis clear. It is a matter of immense importance to make an early diagnosis of pulmonary tuberculosis before the lung has become extensively invaded, and our patient has become a source of infection to others, as our only hope of controlling this disease is in its early and prompt treatment, climatic or otherwise. Tubercle bacilli, according to Musser, are frequently found when the physical signs and symptoms would only excite a suspicion of tuberculous infection. We must not wait till our patient has become emaciated to the last degree and comes presenting signs of a cavity, with consequent fever, night-sweats and cough. Microscopical examination of the sputum, while affording confirmatory evidence of the nature of the infection in such a case, is hardly to be considered necessary.

It is also worth remembering in this connection, as illustrating the value of regular systematic examinations of the sputa of all cases of cough extending over a few weeks, that occasionally cases of tuberculosis are met with in the upper air passages, before there is any infection of the lungs discoverable by any of our methods of examination, save the microscope. The writer well remembers a case of suspected syphilis from the situation and character of ulcers on fauces and pharynx, that only a microscopical examination of the sputum afforded the clue to the correct diagnosis of tuberculosis. In this case it was some months later before any pulmonary signs of involvement could be discovered. If the examination of the sputum is negative, recourse can be had to a blood examination when either the plasmodium of malaria is discovered, or the characteristic Widal serum reaction of typhoid fever is obtained.

The Widal reaction can be made by the general practitioner if he can gain access to a laboratory for a fresh, living broth culture of the typhoid bacillus. If this cannot be obtained, a formalized dead culture may be employed. Ehrlich's diazo reaction, although present in other diseases, is of much diagnostic value, especially when found in conjunction with negative blood and sputa examinations.

The general practitioner should familiarize himself with the recent advances made in the pathology of the blood. Blood examinations, as a method of diagnosis and rational treatment, whether medical or surgical, have, of late years, been used more frequently and have demonstrated their value beyond dispute. By hemanalysis, in various morbid conditions, we can discover deviations from the normal in the number, size, shape, and color of the red cells, the presence of nucleated red cells, an increase or decrease of certain elements of the white blood corpuscles and the presence of cell bodies not usually found in the peripheral blood. Also variations in the amount of hemoglobin and finally the presence of parasites and bacteria in the cells and in the blood stream. These pathological changes in the blood bear definite relations to various diseases that could not be distinguished by any other methods of diagnosis. Many of the anemias cannot be differentiated without a blood examination, as the pallor, symptoms and physical signs may be identical. The value of any form of treatment, in these conditions can also be obtained by systematic hemanalysis.

Simon, in a recent paper, has emphasized the necessity of examining the blood in suspected cases of lead poisoning. In 20 persons exposed to the action of lead, whose blood he examined, two only presented active symptoms, such as lead colic and wrist drop, three others had indefinite colicky pains some years before, and three complained of wrist weakness, the remaining 12 gave no signs of lead intoxication. All of these cases, however, showed the presence of basophilic granules in the red blood cells. Even in light exposures Simon found these granules, and their number was directly proportionate to the severity of the intoxication. An increase of these degenerated cells was found to precede the appearance of clinical symptoms of poisoning. A regular examination of the blood of lead workers would suggest appropriate treatment before profound intoxication occurred.

Basophilic degeneration is of diagnostic importance in all conditions in which hemolytic poisons are operating in the body and in pernicious anemia are an indicator of the severity of the disease. It is also found in malarial and cancerous cachexias and in various septic conditions.

Leucocytosis.—The phenomenon in the circulating blood known as leucocytosis, when persistent and consisting of an increase of the white blood cells, known as the polymorphonuclears, is a pathological condition. It occurs in many infections and is of great diagnostic value. In all morbid processes due to pyogenic organisms such as appendicitis, abscesses, osteomyelitis, pyosalpinx and inflammation of viscera and serous membranes it is marked and constant. Its absence in certain affections in which we would naturally expect it to occur is from a diagnostic

standpoint an important symptom. It does not occur in uncomplicated typhoid. Simon maintains that if present in a suspected case of enteric fever it is more than probable our diagnosis is wrong or some complication exists. It is absent in malaria, most cases of influenza, measles and tuberculosis, unassociated with a secondary pus infection. Its diagnostic value is seen in the consideration of cases which simulate either typhoid fever or appendicitis. A blood count enables us to differentiate. If found during the course of typhoid fever it may give us warning of an impending perforation and indicate operation and the consequent saving of our patient's life.

According to Simon, the number of leucocytes in any acute infection is directly in proportion to the intensity of the infection, and the resisting powers of the individual affected. Where no leucocyte increase occurs in a virulent infection it would indicate a lowered resisting power of the individual and be of grave prognostic import. Death from pneumonia almost invariably occurs when this phenomenon does not develop; the exception only being found in the mild infections in which it is not present.

Dr. Thomas R. Brown, of the Johns Hopkins University, has recently answered the criticisms of Dr. Deaver and others as to the practical value of this method of diagnosis in surgery. He considers its presence or absence as determining whether the surgeon in any given case is dealing with an inflamed appendix, or merely some hysterical condition, or with a floating kidney, a biliary or renal calculus. It serves as a guide to the severity of the infection; when the count is above 12,000 or 20,000, an operation is imperatively demanded; if below, the observer can wait, and by further systematic counting, determine whether the case is going on to recovery or perforation is impending. Dr. Brown further believes that no operation should be undertaken without a blood count and if a severe infection is found unassociated with a corresponding degree of leucocytosis, operative measures will be useless.

The iodine staining reaction of the leucocytes is found in many cases of toxemia and is generally associated with a leucocytosis. It is of value in the diagnosis of septic conditions and when present in a marked degree indicates a profound intoxication, and if unaccompanied with a leucocytosis would be a sign of grave prognostic import and would contraindicate extensive operative interference in pus cases. An increase of the eosinophilic leucocytes in the circulation, is found in many pathological conditions. In bronchial asthma, they are increased 10 to 20 per cent. and thus serve as a means of differentiation from cardiac and renal asthma in which they are absent.

Dr. T. R. Brown was the first to observe this phenomenon in the acute stage of trichinosis, and in the first series of cases he reported, the eosinophiles varied from 42 to 68 per cent. of all the white blood corpuscles present—an enormous increase. Fever, gastro-intestinal disturbance, diarrhea, and muscular pain and tenderness following the ingestion of raw ham, pork or sausage, when associated with marked eosinophilia should excite a suspicion of trichinosis and a piece of the shoulder or calf muscle should be removed and examined for trichinæ.

Malaria.—Many practitioners are in the habit of calling all diseases accompanied with a periodicity in the symptoms malarial, but a blood examination for the parasites in many cases would show their absence. The diagnosis of malaria covers a multitude of diagnostic errors and should never be based on the clinical symptoms alone, as the initial chills of tuberculous and pus infection have been mistaken for it.

Typical malarial intermittents are readily diagnosed, but in the atypical forms and more especially in the pernicious varieties of infection, serious errors in diagnosis may occur. In the late Spanish War most of the cases of fever proved to be typhoid, and had blood examinations been made of the infected soldiers in the Western and Southern camps the mistake of confounding this disease with malaria would not have happened. A clinical diagnosis should, in every instance, be confirmed by an examination of the blood, which may be tedious if the parasites are not abundant, but if the disease is malarial, they will be surely found; it also determines the *type* of infection present, which is of value in prognosis and treatment. Both Cabot and Ewing state that the examination of the fresh blood is the readiest method of discovering the organisms, and this is best done just before the expected chill when they have reached their greatest size. This method takes but a short time and is applicable to the bedside, office or dispensary and shows the ameboid movements of the pigmented intracorpuscular forms of the parasites, with the active rapid motion of the pigment granules, together with any phagocytosis on the part of the white blood cells that may be taking place, also any of the actively motile flagellating bodies, if present, can be recognized. Its limitations have been found by Ewing to be in the study of the early small unpigmented forms, these being more readily found in the stained smears. Stained blood films, show us better than the fresh specimens the minute structure of the parasites and can be kept for reference. Several methods of staining can be used, as the organisms take readily all the basic aniline dyes. Wright's stain, described in January (1902) number of the *Journal of Medical Research*, has been found by the writer to be of great value in staining the parasites as well as the blood cells. It is durable and improves on keeping, the writer has modified this stain somewhat, by using a saturated unfiltered solution, which gives better results in his opinion.

Atypical cases of malarial infection occur more frequently in the estivo-autumnal than in the tertian types. Masked malaria, in which the symptoms are obscured by other complicating diseases, and latent malarias, which exist without

producing any appreciable symptoms, but in which the parasites can be demonstrated in the blood, are of this type. In some cases the temperature may be little above normal or even subnormal, although the infection is a grave one.

This emphasizes the importance of routine blood examinations in individuals coming from known infected districts, as Dr. Craig, U. S. Army Surgeon, stationed at San Francisco, in a recent work on estivo-autumnal fevers, states he found large numbers of parasites in the blood of soldiers returning from the Philippines with few or no symptoms present. In the masked forms, symptoms referable to other infections such as diarrhea, acute and chronic dysentery, pneumonia, typhoid, hepatic abscess, pulmonary tuberculosis, chronic gastritis, melancholia, insanity and rheumatism were present.

Dr. Craig gives the history of a case of pernicious malaria of this tropical type in a young girl not away from San Francisco in over two years. He considered the infection might have taken place from a mosquito that had imbibed the blood of a soldier from the Philippines, with the disease, and that there is grave danger of severe malarial types of infection becoming endemic in any locality in which there are large numbers of infected subjects with tropical malaria, provided the ubiquitous *Anopheles* mosquito is present.

Malaria in children rarely follows a typical course, but occurs in masked and irregular forms, which present symptoms of fever, headache, drowsiness, vomiting and constipation, which may excite a suspicion of meningitis, or cough, rapid breathing and râles may simulate a pneumonia. The quotidian form is most common, but there is seldom a complete attack of chill, fever and sweat, the chill often being absent, or if present, so slight as to be overlooked. In the cases observed by the writer, gastro-intestinal disturbances were the most common symptoms; some slight fever, headache and drowsiness were also present. The attacks came on suddenly, sometimes when the children were at play, and in other cases at night, when in bed, and began with vomiting, followed by a watery diarrhea, headache, drowsiness and fever, which subsided after some hours, and they appeared perfectly well, until the next attack. Several of these cases had gone for a long time without recognition and showed a marked malarial cachexia. Blood examinations, in all of them, demonstrated tertian parasites in large numbers.

Puerperal Sepsis.—In cases of puerperal sepsis, we have an endometritis, which is either of the putrid or septic variety. It is a matter of considerable importance to determine which form is present, as the treatment is largely influenced by the type of infection found. In many cases the clinical symptoms will be our guide, but the only method by which we can arrive at a positive conclusion is by taking cultures from the interior of the uterus by means of a glass tube, first introduced by Döderlein. By this means we are enabled to know within twenty-four hours whether we have to deal with a streptococcic and dangerous infection or whether we have present merely a sapremic condition comparatively harmless. In the one case antistreptococcic serum is indicated, possibly a hysterectomy to remove the infected uterus, in the other curettage. In the former case the employment of the curette could only do harm by destroying nature's wall of leucocytes thrown out as a barrier to the further ingress of infection. It must be remembered that the lochial discharge, in streptococcic infection, may not be foul smelling, as putrid endometritis is not present. In sapremic conditions the reverse is true, the bacteriological findings are necessary to clear up the diagnosis.

In many acute cases of gonorrhea the character of the infection is self-evident but in others, especially in chronic cases, it is a matter of vital importance to discover the presence of gonococci. It is a matter of a few moments only, to make a smear, fix stains and examine for this most persistent and annoying organism. No case should be considered as recovered unless repeated examinations of the urethral secretions fail to show them present. Leucorrheal discharges, when persistent, should be examined for this organism. In purulent otitis media the character of the pus organisms should be determined, if the *Streptococcus pyogenes* or pneumococcus is found there is much liability of mastoid involvement.

The diagnostic value of the pneumococcus is now freely established and it can at times be recovered from the sputa before the physical signs of croupous pneumonia are discoverable. It will materially increase the chances of recovery of our patient, if thus early we are fully aware of the serious nature of the impending disease, and are able to conserve his energies for the coming struggle.

In malignant pustule or anthrax the *Bacillus anthracis* can frequently be discovered in the pus without resorting to cultural growth. The chemical analysis of the gastric contents obtained after a test meal by the stomach tube is of great diagnostic value and should be more used by the general practitioner. The passage of the tube is easy, requires no special skill or special training and only the unconquerable repugnance of a patient, or some morbid condition, such as aneurism or gastric ulcer, should preclude its use.

The secretory and absorptive functions of the stomach, also motor insufficiency, due either to atony or structural alterations of its walls, can readily be discovered. The gastric juice should be examined for the reaction, presence of hydrochloric acid, lactic acid, pepsin and rennet ferments, products of starch digestion, mucus, bile, blood, pus and intestinal parasites. Pieces of the gastric mucosa may be occasionally found after the stomach washing. Microscopical examinations of these, may, according to Einhorn, help to supplement a diagnosis. Particles of tumors are sometimes discovered, especially when a malignant growth is at the cardiac orifice.

The persistent absence of hydrochloric acid and digestion leucocytosis, together with the presence of lactic acid, the Boas-Oppler bacillus and other evidences of motor insufficiency are strong presumptive signs of carcinoma, even in the absence of any tumor, felt by abdominal palpation.

The microscope occasionally reveals the presence of the mycelium and spores of the mold fungus introduced into the stomach through food and drink, especially in cheese. The fungus exists in these ingesta in minute quantities and in the spore forms. In the gastritis present in these cases, highly irritating organic acids are found.

In protracted cases of dysentery, especially in those coming from the tropical or subtropical districts, the feces should always be inspected microscopically for the *Amœba coli*. If found, successful treatment can be instituted and our patient be spared the further complication of liver abscess.

In obscure cases of gastro-intestinal disease, we should not be content with the clinical symptoms alone, but supplement these with an examination of stomach contents and feces. Careful sifting of the feces will often reveal the presence of one or more gall-stones, as icterus does not occur in many cases of cholelithiasis.

In cases of advanced anemia, commonly attributed to malaria and insufficient food, especially in those met with in our Southern States, the question of the presence of uncinariasis or hook-worm disease should always be considered.

To Dr. C. W. Stiles, of the Marine Hospital Service, the profession is indebted, for the discovery of these intestinal parasites, not at first considered native to this country, in the poorer white population in the South, a class frequently referred to as "the poor white trash."

The clinical picture of this disease with the anemia and progressive emaciation, the cardiac symptoms, the edema of the face and ankles, the increased pulse and temperature simulated many morbid conditions, so that many cases were thought to be malarial anemia, valvular heart disease, nephritis and rheumatism. The blood examination revealed the condition known as eosinophilia and a high grade of secondary anemia approaching the pernicious form, but a microscopical examination of the feces showed the presence of the ova and embryos of the parasites in numbers varying according to the severity of the infection.

In the brief time at his disposal, the writer has merely indicated but a few of the many applications of these laboratory aids and, in conclusion, gentlemen, permit me to earnestly urge on such of you who have not as yet made use of them; an early investigation and trial of these means of precision in diagnosis.

Mr. Phipps Gives $20,000 for a Building for Consumptives. Henry Phipps has given the Johns Hopkins Hospital, through Dr. William Osler, $20,000 for the purpose of establishing a separate out-patient department for consumptives at the hospital. This announcement was made last week by Dr. Osler.

MEDICAL PROGRESS.

MEDICINE.

Importance of Normal Intestinal Bacteria.—That bacteria are essential to life is evident from certain experiments, demonstrating how difficult it is to rear animals with sterile food. This is especially the case where the normal food is rich in cellulose, which requires more than any other substance, bacterial activity for its disintegration. J. Strasburger (Münch. med. Woch., Dec. 29, 1903) states that it is impossible to render the intestinal tract of the higher animals and man free from germs. Even in polar regions, where bacteria are certainly scant, the intestines contain large numbers. They are responsible for the fermentation in the small bowel and the putrefaction in the large, and the two processes are sharply demarcated from each other at Bauchin's valve. If the alimentary tract is placed into concentrated sublimate solution soon after death, it will turn green above the valve, due to bilirubin, and red below it, owing to hydrobilirubin, resulting from bilirubin by putrefaction. The absence of putrefaction in jejunum and ileum is a wise provision of nature for here the intestinal contents are rich in proteids, which, when absorbed in a decomposed condition, would rapidly cause intoxication and the urine would soon be charged with indican and ether sulf-acids. The intestinal flora is in the main the same in the small and large intestines, but the presence of sugar in the upper part of the alimentary tract plays an important part in preventing putrefaction and in allowing germs capable of setting up fermentation, to gain the upper rand. It is here that many pathogenic germs, accidentally ingested, are destroyed, provided a healthy general condition prevails; the *Bacillus coli* and *Bacillus lactis aerogenes* must thus be regarded as safeguards against disease. Another important function of bacteria is their influence upon peristalsis. Disadvantages resulting from the contaminated intestinal mucosa are few and chiefly concern themselves with a loss of valuable nitrogenous material which naturally goes on with every bacterial proliferation.

The Prolongation of Life.—The consideration of this problem has been a topic for reflection and study since the dawn of thought. Sir Hermann Weber (Brit. Med. Jour., Dec. 5, 1903), states that the diminution of infant mortality and the improvement of the hygienic conditions have raised and will continue to raise the average duration of life. Galen, Cicero and others wrote almost as wisely in the ancient days as modern authors have done. Nevertheless there is a great difference between the old writings and the new. This is due to the immortal services of Jenner, Pasteur, Lister and Koch. From the recent reports of the Register Office of England, it appears that we are justified in assuming that though life is usually limited to eighty years it may be occasionally prolonged to a hundred or even more by the operation of certain internal and external agencies. By studying these we may eventually be able to prolong the lives of many individuals beyond a century. The author reports the result of his examination into the records of more than 100 cases of long-lived persons and concludes that the majority of them were temperate, that they were small meat eaters; that they lived much in the open air; led an active life, often one of toil with great restrictions as to food and comforts; that most of them were early risers; that a great many of them had a joyful disposition and performed their work cheerfully and that only a few were intemperate or idle and lazy persons. The tendency to early death is just as hereditary in some families as longevity, and

these individuals it is whose lives by judicous adherence to the regimen above cited can be most favorably influenced. Saville has shown that death from old age is caused by a kind of atrophy of the tissues and organs connected with the changes in the blood vessels, and the atrophy of the hematogenic glands. Life, in other words, depends to a rgeat extent on the organs of circulation. These questions have received especial attention from Ludwig and Sir Lauder Brunton. Mosso has shown by his ingenious balance on which a man is placed in the horizontal position, that during the act of thinking the head becomes heavier from a rush of blood to it. Walking is the natural exercise of the body and Oertel's method of mountain climbing has shown what a profound effect it may have on the human frame, especially upon circulation. Nor is the week end holiday unimportant. Martin Luther's motto, "Rast Ich so Rost Ich" (If I rest, I rust), is true, but the wear of exercise is more than compensated by the increased supply. Of foodstuffs the author says that adult healthy persons do not need alcohol. The average duration of life in Owen's reports comprising 4,284 persons, was greatest among total abstainers. Very few moderate drinkers living as long and almost no one who had been a hard drinker passed beyond late mid-life. Tea and coffee are considered by the author to be valueless, coffee, because of the volatile oil being more injurious to digestion than tea. Snuff-taking is now out of fashion, but many old doctors maintain, not without some reason, that snuff prevented many forms of frontal headache and acted as a valuable stimulant to the capillaries of the Schneiderian membrane. Massage is important, not alone with the general body, but of localized parts. Friction of the thyroid is probably useful in maintaining general energy. Massage of the scalp retards loss of hair and prevents some forms of headache.

Primary Tuberculosis of the Tonsil.—This subject is discussed by S. Ito (Berl. klin. Woch., Jan. 11, 1904), who also reports two cases, where autopsies were made and no tuberculous foci found, except in the tonsils. These foci were localized in the lacunæ of the pharyngeal tonsil and rarely on the surface. This, together with the examples of secondary tonsillar involvement, which the author has seen, leads him to claim that the diagnosis of these cases can only be made from microscopical examinations. The rarity with which the condition occurs may be attributed to the fact that the tonsils probably offer little resistance to the passage of the tubercle bacilli, and therefore do not themselves become diseased. As a rule tuberculosis of the tonsils runs a mild course without forming any ulcerations. It is also claimed that the tonsil affords a means of entrance to the tubercle bacilli in the numerous cases of cervical lymphadenitis and the fact that the tonsil is not itself involved is explained by the author as follows: (*a*) As already stated, the bacilli are known to be able to pass through the tonsil without causing any local changes, and (*b*) the primary focus in the tonsils may become healed at an early date. If a localized extension does take place it may be attributed to a lessened power of resistance or some particular predisposition on the part of the patient.

Malaria; Epidemiology and Treatment.—The discovery of the part played by the *Anopheles* in the dissemination of malaria has not by any means solved the epidemiological problem, but, as might have been expected, has merely paved the way to that consummation. Large numbers of important accessory problems have cropped up, and the new light which has recently been cast upon these by the almost unparalleled experience of Celli (Arch. f. Hygiene, 1903, Heft 3), certainly brings one measurably closer to the goal. He points out that an essential element in the study of malaria epidemics is to distinguish between the recurrences due to previous infections, and the fresh cases, as also between the various forms of parasite involved. The difficulties connected with making these distinctions are often considerable. Latent malaria can at present be detected by no known test—neither by agglutination nor by hemolysis, as had been hoped. The microscopical detection of the latent forms of the parasite is very uncertain. The sexual forms are often not to be found in the circulating blood during the latent intervals, and lienopuncture is too dangerous to be resorted to as a diagnostic procedure. The clinical features seem actually to be of more moment in deciding this problem than any other. In general, if the infection is double or triple, recurrences are apt to be more frequent and obstinate. If a given attack of malaria is persistently followed by malaise, weakness, anemia, and splenic tumor, it is safe to conclude that the infection has not been banished. There are also certain factors which strongly predispose the recurrence—namely, deficient nutrition, severe labor, "catching cold," and other diseases. The study of the relation maintaining between the epidemics of recurring disease and those of fresh infections afford certain very interesting and puzzling comparisons. The former always begin somewhat before the latter—the so-called "pre-epidemic" increase. Moreover, in any given locality, either one of them may be very severe, and the other very light. The epidemics of fresh cases show an annual curve which varies according to the parasite: The light tertian forms begin in the spring, even as early as March in Italy, the severe tertian and estivo-autumnal forms make their earliest appearance in summer, while quartan fever is chiefly an autumn disease. The study of the curve of the epidemics as such, which has yielded such remarkable results, has been supplemented by that of the relationship between the mosquitoes and the infections, with no less strange an outcome. In general, it is found that the extent and severity of malaria epidemics in any given region show no relation to the extent of swamp-land and of anophelismus. Moreover, the study of mosquitoes in successive years shows an apparently highly variable susceptibility to the disease, thus in 1902, in Vico, of 630 mosquitoes investigated, only three were found to be infected. Celli concludes that the insects possess an acquired or natural immunity against the disease, which lasts for a varying length of time, sometimes apparently over centuries. A very large number of studies were made, with the assistance of the Italian government, upon the treatment, prophylactic and curative, of the infection. Quinine was used during the latent periods, experiments being made with all its available salts in every practicable form of administration. It was found that the percentage of recurrences may be considerably curtailed by an energetic "interval" treatment, yet a fairly large proportion of cases are not affected thereby. Celli considers that excepting quinine all other medicaments are powerless against malaria. For the secondary anemia, quinine, supplemented by good feeding, also affords the best treatment. The prophylactic treatment by quinine of individuals previously not infected has met with a very full measure of success. On the other hand, the efforts to exterminate the mosquito by sanitary engineering is regarded by Celli as almost futile and chimerical. It involves too great an outlay of money, which is likely to be wasted.

SYPHILIS IN OUR COLONIES.

In proportion to our territorial aggrandizement our interest must grow in this somber but important matter. E. Jeanselme, discussing in the *Revue Française de Medicine et de Chirurgie*, the prevalence of the disease in the French colonies, calls the attention of all colonizing nations to it as a very serious problem. At the present moment, he says, "certain races remain immune, viz., some tribes of Central Africa and of New Guinea and the savage and little known dwellers among the mountains of Laos." There is, however, as opposed to this, a territory overwhelmingly large, whose population in recent years has been decimated by syphilis. This is particularly true of certain parts of Central China. The luetic plague has been less austere in Japan and in the Malay archipelago and in Hindostan. In Siam, according to Deuntzer, syphilis is present in 75 per cent. of the male European population. In the same country, among the upper native classes, a man who has not had syphilis is a rarity. French Indo-China has suffered to a like extent. This explains the frightful ravages of syphilis among the European troops who garrison these countries, and although in those regions where the infection is not of recent origin, the character of the disease need not necessarily be more severe than we are accustomed to encounter here, it is on the whole a more virulent disease than that seen in the temperate zones.

The gravity of syphilis in the tropics is determined by various factors, the most important of which probably centers in the resisting power of the race to which the individual belongs. It is said that certain of the blacks of the Malay region enjoy relative immunity, but this is by no means true of all.

In the Philippines the syphilitic infection is characterized by peculiar malignancy. This is of ultra importance to us, because the time may not be distant when we shall send large numbers of young men into that region. Throughout the Tropics it is peculiar that the primary infection is very often extragenital. The explanation for this is that excoriations of the body are relatively frequent, because very few clothes are worn. Furthermore it is possible that some of the numerous tropical insects are active agents in spreading the contagion. Again, the modes of life which characterize the hot countries, the single utensil which carries the rice, the common pipe and water-dipper, which circulate from mouth to mouth, as well as other like factors are important agents of infection. The truth of this is evident by the startling frequency of labial chancres. These facts, which tend in a measure to eliminate syphilis from its usual environment and to place it among the diseases to which all may be almost equally prone, make it very desirable that measures should be taken for its control in our territorial acquisitions.

In the Far East it has been noted that syphilis has usually been carried from place to place by itinerant Chinese merchants. This is particularly true in Siam, where, in centers which have been the seat for many years of a sort of Chinese mercantile invasion, it is certain that at least half of the inhabitants are the loathsome victims of malignant syphilis.

In concluding his able paper, the author urges that immediate prophylactic measures be taken for the safeguard of the French colonies from further contamination. With this end in view, he suggests that all civil and military officers, all missionaries and others in any way connected with the government, should be instructed as to the gravity of the syphilitic peril and be taught how to recognize and combat the characteristic lesions of the disease. All colonial physicians in government employ should, he urges, receive special instructions in venereal hospitals in order to en-

able them to diagnose the rarer forms of syphilis.

With our marine hospital service, probably leading the world in the administration of prophylactic medicine, we shall not long be without reports of work done in this important field.

IMPORTANT MEDICAL LEGISLATION.

Two bills relating to important subjects in medicine, one already introduced, the other about to be introduced into the New York State legislature, were under consideration at the recent annual meeting in Albany of the Medical Society of the State of New York. The most important of these was that with regard to the licensing of opticians in order to permit them legally to prescribe glasses for those who seem to need them. The other concerned the regulation of the name and seal of certified milk except in connection with milk that had been actually examined and pronounced worthy of certification by properly constituted boards of health or committees of medical societies. Though demanding very opposite treatment neither of these measures should be neglected by the profession. Medical men who are in a position to exert influence on members of the legislature should employ it for the purpose of hindering the passage of the first bill and assisting in the passage of the second.

The optometry bill, as it is called, has come up in one form or another several times and in many States. Dr. Wiesner, of New York, called attention to the fact that asthenopia was becoming much more common in crowded city life, under the stress of the severe competition which now characterizes modern existence. Scarcely a block of the business portions of our cities fails to display at least one sign of an optician who measures for glasses and directs people with regard to the care of their precious organs of vision, though as a rule he knows nothing more than how to place spectacle lenses in frames and judge of the results produced in the facilitation or obscuration of vision. As is easy to understand, most of them have absolutely no knowledge of the eye and no idea of the serious lesions and complex pathological conditions that may constitute the basis of the dimness of vision for which they so glibly pronounce the word glasses and proceed to measure the patient therefor. It is almost as if the eyes were like the feet and needed no more skill in fitting them than the shoemaker has in fitting shoes. As a matter of fact the refracting optician not infrequently knows much less about glasses for the eyes than the shoemaker does about shoes.

A recent attempt has been made to gain influence for the optometry bill by sending out circulars, enclosing a postal card, which the doctor is expected to sign and return. The circular is a curiously interesting and specious presentation of the optician's side of the question of refraction. We doubt not that many physicians who did not realize just what the real question at issue was have already signed these postal cards and returned them to the committee of business men having the optometry bill in charge without realizing that by so doing they were actually encouraging the passage of a measure that derogates from the importance of the most delicate and demanding of specialties in medicine, one of which requires the widest knowledge and the best of judgment. After all the prescription of glasses can never be the work of a mere artisan. It must always be a serious professional duty. No prescription that a physician can write may do more good than a proper measurement for glasses, but, on the other hand, no prescription can do more harm than the recommendation of lenses that are not suitable for the eye under consideration.

It is not necessary to recall many serious injuries that have been inflicted by the untrained optician. Many a patient who would probably never have to wear glasses and whose original complaint required local treatment instead of a prescription for lenses is condemned to the use of spectacles as the result of having worn them for a considerable period on the recommendation of some refracting optician who knew no better. It is the optician's business to sell his glasses. Like the advertising specialist who charges nothing for his services, but whose medicines must be purchased at a high rate before the patient leaves his office, the optician must fit his patient with glasses in order to recompense himself for the time spent in studying the patient's eye. It is important then that not the least encouragement should be given to the present unfortunate abuse which it is to be hoped will before long, with many others, be removed as the result of union in the medical profession here in New York State. As for the physicians who have been fooled into signing the postal card and returning it without realizing the measure that they were encouraging, perhaps this will serve as a lesson that in matters of this kind too great care cannot

be exercised and that it is for matters of this kind that medical journals should be consulted.

As regards the other piece of proposed legislation, the guardianship of the certification of milk, there is no bill pending that is likely to do more good. The improvement of the milk supply of the cities of this State as the result of the certification of the products of certain carefully examined dairies and farms has brought about a reduction in infant mortality greater than any other measure ever attempted for that purpose. If, however, milk producers or wholesalers are allowed to falsify certification and claim official approval where it has not been given without fear of legal punishment, much of the good that has been secured will be lost. The bill making such falsification a misdemeanor deserves every encouragement and will, it is hoped, be promptly passed by the legislature. It is minute details of care like this that mean very much for the health of the infants of our cities' poor. No effort should be spared then further to safeguard and secure the permanency of the reform in milk collection and distribution which has thus far proved so effective.

SURGICAL INTERVENTION IN TYPHOID PERFORATION.

ON April 7, 1884, a man, aged forty years, who was seized with unmistakable evidences of intestinal perforation during an attack of ambulatory typhoid, was operated upon by Von Mikulicz. Pieces of potato were floating about in the man's belly. He ultimately recovered.

Recently Drs. R. H. Harte and A. P. Cooper Ashhurst, of Philadelphia, presented a compendious monograph on the subject of intestinal perforation, which reviews not alone the history of the condition, but gives the most modern results and the most recent technical methods. Intestinal perforation is said to occur in from one to eleven per cent. of cases of typhoid fever, the average of nearly nine thousand cases reported by various authors being 2.5 per cent.

The etiology of perforation has been given very careful attention. Whites are more prone to perforation than blacks. It is more common in the male sex by a ratio of four to one. Over one-half of all cases have occurred between the fifteenth and the thirtieth year. Intestinal parasites, always predisposing in their influence, have, with certainty, occasionally acted as the exciting agent of perforation. The stage of the disease and its severity bear a definite ratio to the incidence, more than half of all perforations occurring during the second and third weeks, and while Osler says "There is certainly no relation between this accident and the severity of the disease, others believe on apparently as good authority that perforation is more apt to occur in the ambulatory than in the classic forms.

Pathologically, Mallory has shown that the so-called "typhoid cells" consist of endothelial cells which have become gorged with leucocytes. The process of formation of these typhoid cells continues, and if the infiltration does not dissolve, the affected area is cast off into the bowels by necrotic action. Ischemia and toxemia aid in this process. Undoubtedly a great many of these ulcers perforate the serous coat but are not heard from for the simple reason that the ever alert peritoneum protects the individual's life by soldering the rent with fibrin; the gut may become attached to a neighboring coil, or the surgeon's friend, the omentum, may wrap itself about the part and prevent contamination. It is rare that perforations are multiple, indeed the number is so small that it is a question whether one should not be justified in ceasing to search for further lesions after one has been found.

The most important symptoms are pain, vomiting, temperature, delirium, rigidity, pulse and respiration, facial expression, tenderness, dulness and edema of the abdominal walls. From these symptoms, which in most cases are vague and unreliable, a differential diagnosis most frequently has to be made from appendicitis, peritonitis, intussusception, cholecystitis, gastric ulcer, suppurating mesenteric glands or splenic infarcts.

The treatment, according to the review of Harte and Ashhurst, of all patients suffering from intestinal perforation in typhoid fever should be by laparotomy. To trust to medical treatment alone is "nothing short of folly." According to the calculations of Briggs (*American Journal of the Medical Sciences*, May, 1903), more than 16,000 perforations of the intestine due to typhoid occur annually in the United States alone. What must be the total mortality from this appalling disaster the world over? Of this stupendous sum of 16,000 all died save fourteen. The mortality is thus, in cases demanding operation, 100 per cent.

The choice of the anesthetic is not unimportant. Many surgeons have advocated the free use of massive infiltration. While theoretically,

at least, this may be as efficacious in preventing shock as general anesthesia, the fact remains that it cannot prevent psychical shock or give that relaxation to the abdominal muscles that is so desirable. A few whiffs of chloroform or ether usually suffice in the debilitated state of the patient to effect complete narcosis.

Speed, from the time the knife is taken in hand, is as essential in this operation as in that of Cæsarean section. The incision is best made to the right of the median line over the cecum. The deep epigastric is not apt to be wounded and that part of the small gut most often affected is, by this pathway, most thoroughly exposed. The cecum should be located at once. The appendix should be removed if necessary. A large number of methods have been devised for the treatment of the perforation, but it is conservative to say that the majority of them can be best handled through infolding by a purse-string suture. Similarly there exists much diversity in opinion as to the most judicious method of affecting the toilet of the peritoneum.

The analysis of 362 cases shows a mortality of 74 per cent. Those perforations, which were under one-eighth of an inch in diameter, gave a mortality of but 51.3 per cent. Those under one-half inch a mortality of 76.7 per cent. Those over one-half inch of 69.5 per cent. The time elapsing between perforation and operation presents an interesting problem. Of those operated within half an hour of perforation, the mortality was 100 per cent.; within one hour 100 per cent., after two hours 66 per cent., after three hours 25 per cent., after four hours 85 per cent. After seventy-two hours the ratio again drops to 55 per cent. After two weeks it is but 50 per cent. It would seem from this that the most favorable time was about three hours after perforation, although the number of cases upon which these statistics are based is not yet sufficient to make such a conclusion positive.

Without going further into the details of an operation which has been exploited by some and condemned by others, it is sufficient to say that this monograph presents facts which should be known to the entire profession of the land. If 16,000 people perish annually from intestinal perforation in the United States alone, and if from an analysis of 362 cases, more than one-quarter were saved from certain death, the most conservative practitioner must be forced to agree with the statement of the authors: "To trust to medical treatment is nothing short of folly."

ECHOES AND NEWS.

NEW YORK.

Appointment at Mt. Sinai Hospital.—Dr. Samuel M. Brickner, who for many years has been associated with the Gynecological Department of the Mount Sinai Dispensary, has been appointed Adjunct Gynecologist to the Mount Sinai Hospital. Dr. Brickner's active service begins with the opening of the new hospital buildings in March.

X-Ray Prize Essays.—Believing that the further development of X-rays is of great importance to surgery and medicine and the human race, and to encourage research and disseminate the knowledge gained, the *Illustrated Review of Physiologic Therapeutics* offers the sum of $1,500 in cash prizes for the best essays on X-rays in Medicine and Surgery, the first prize being $1,000. All surgeons, physicians and hospitals interested in any branch of X-ray work should write to the *Illustrated Review of Physiologic Therapeutics*, 19 East Sixteenth Street, New York City, for information concerning title, time allowed, conditions, etc.

Civil Service Examinations for the State and County Service.—The State Civil Service Commission announces general examinations to be held February 27, 1904, including the following positions: Physical instructor in State institutions; physicians in State hospitals and institutions of both regular and homeopathic schools. Applications for these examinations must be made on or before February 22. Full particulars of the examinations and blank applications may be obtained by addressing the Chief Examiner of the Commision at Albany.

Clean Money.—Dr. Darlington, President of the New York Board of Health, was heard Jan. 29, by the House Banking and Currency Committee on the pending bill providing for the issue of new notes to the end that the paper currency may be retained in good sanitary condition. Dr. Darlington explained that he was engaged in an investigation to ascertain whether old circulating notes are mediums of transmitting disease germs, a fact that is fully believed by physicians. The doctor believes a provision for keeping the paper money of the country as clean as possible by constant renewal would be a step in the right direction.

PHILADELPHIA.

Dinner to Dr. Hinsdale.—Members of the medical profession tendered a farewell dinner to Dr. Guy Hinsdale at the Union League, Friday evening, January 29, previous to his departure for Hot Springs, Va. Dr. James Tyson acted as toastmaster.

Assistant Medical Inspectors.—Considerable disappointment has been felt over the failure of the Department of Public Health and Charities to appoint 31 assistant medical inspectors in connection with the plan for the reorganization of the Bureau of Health. It is now stated that at the examination held some three weeks ago more than 200 physicians attended, but that only about 60 attained the required average. This was more than enough to fill the appointments, but as the ward leaders were to make the selections and some wards had several successful candidates and others none, there resulted only the filling of places in a part of the city. A second examination has been held and the names of the physicians to receive the appointments will be announced in a few days.

Development of the Rest Treatment.—At the meeting held in celebration of the twentieth anni

versary of the organization of the Philadelphia Neurological Society on January 20, Dr. S. Weir Mitchell gave a very interesting résumé of "The Mental Processes by which the Rest Treatment was Developed." The beginning of the chain of circumstances which finally led to the adoption of the treatment was laid during the Civil War. Dr. Mitchell then noticed the cases of acute exhaustion occurring among the soldiers after or during forced marches, this being seen particularly in the Gettysburg campaign. These men remained for weeks or even months in a condition which would now be called neurasthenia. It was noted, however, that complete rest and forced feeding brought them up so that in many instances they were able to again join the ranks. Some time after the war a man who was under treatment for locomotor ataxia fell and broke a leg. This kept him in bed for three months, and as soon as he was out he broke the other leg, this enforcing a second rest of three months. When he finally recovered the use of his legs it was seen that the ataxia was decidedly improved. In 1874 Dr. Mitchell was consulted by a married woman, aged twenty-six years, who was exhausted primarily by much charitable work and the bearing of children in rapid succession. Having ample finances she had tried every known means for the restoration of health, but at the time mentioned was a pitiable invalid. For some time Dr. Mitchell had no better success than had other physicians. He saw that the patient needed both rest and exercise, and recalled the beneficial effect he had seen from the rubbing of people by an old man, who now would be placed in the list of osteopaths and similar performers. A young lady was then engaged for the patient, and by personal instruction Dr. Mitchell developed a system of massage which produced remarkable results. Absolute seclusion of the patient, with massage and electricity, enabled forced feeding to be employed, and rapid restoration to health followed. This first case was discharged in May, 1874. Others followed, and in 1875 appeared the first paper describing the new method of treatment. It was at first received with incredulity and criticism that almost amounted to personal invective. The same reception was accorded the idea in England, where a member of the British Medical Association said that he would rather see his patients die than be cured by such a method. Dr. Mitchell then traced briefly the history of the reaction against this opposition, the use and advocacy of the treatment and finally its world-wide adoption of its principles in the treatment of suitable cases.

CHICAGO.

Crusade Against Tuberculosis.—At the forthcoming meeting of the Illinois State Medical Society, to be held in Bloomington in May, leading physicians of this city will discuss the problems of prevention and cure of this disease, and among the essayists will be Drs. Frank Billings, Geo. W. Webster, H. N. Moyer, Robert B. Preble, and Chas. L. Mix. It is expected that valuable data regarding the ravages of the disease in Illinois will be furnished, also the effect of different occupations on the health of tuberculous patients and the various methods of treatment will be discussed. The statistical features will be confined to the State, and will include mortality, influence of climate, topography, occupation, residence (city or country), and such other data as will be interesting. The symposium will be simply preliminary to more active measures.

Establishment of Antitoxin Plant.—It is stated that Dr. Geo. W. Webster, President of the Illinois State Board of Health, recently said that the antitoxin manufacturers were selling serum as cheaply as possible. This precipitated a discussion which led physicians to adopt a resolution declaring that an antitoxin plant should be established, independently of all commercial concerns. Accordingly, Dr. Robert B. Preble, President of the Chicago Medical Society, has urged that the matter be laid before the City Council. Dr. Webster does not believe there is any law giving the State Board of Health power to manufacture antitoxin, and even if the Board had the power, there were not enough funds to start the work. Dr. Frank N. Walls, Secretary of the Chicago Medical Society, says that it costs Massachusetts 50 cents a thousand units for the serum it manufactures. New York State pays from 30 to 40 cents for its product. Dr. Webster feels sure that the antitoxin firms will supply the serum at the most liberal terms possible. After the discussion a resolution was passed declaring that the condition of the antitoxin market is such as to render it wise to establish a plant independently of all commercial concerns. The City Council has expressed its interest in the matter, and it is believed by a little judicial pushing it might be induced to do something. Dr. L. Hektoen, Secretary of the Memorial Institute for Infectious Diseases, is quoted as saying: "I am authorized to state that if a fund should become available, the Institute will furnish space for a laboratory and ground for stables, provided it is not attempted to furnish serum for any State other than Illinois."

New Hospital for Children.—A new hospital will be erected to take the place of the present Maurice Porter Hospital. It is to accommodate 60 children. Mrs. Julia A. Porter has given $75,000 for the erection of the building. The present hospital was founded in 1882 by Mrs. Porter as a memorial to her son. At first it had 12 beds, but later 31 beds. The new building is to be a modern fire-proof structure, with every facility for the care of sick children. The six requirements of the Children's Hospital Association provide for an observation department, where children are kept two weeks before admission to the wards; an isolation department, laboratory facilities, pure milk supply, bedside and didactic instruction for nurses, and one thousand cubic feet of air for each patient.

Chicago Medical Society.—At a meeting held January 20, there was a symposium on Dietetics. Dr. Fenton B. Turck read a paper on The Dietetics of Atonic Dilatation of the Stomach, in which he discussed the physiology and pathology in relation to atonic dilatation, as well as the therapeutics based on the pathology. He divided the mechanical work of the stomach into three stages: First, distention with food; second, expulsion, and, third, relaxation. He said that the normal resistance at the pyloric end of the stomach increases the tension (lateral pressure), which within physiological limits increases the stimulus to more powerful and frequent contractions. At the end of the digestion the maximum degree of power and number of contractions are obtained. Atony and dilatation may be found as the result of increased resistance in front, such as by stenosis of the pylorus, and cause prolonged overwork and exhaustion of the gastric muscles, or the overwork and exhaustion may be due to the constant and excessive work upon the load within the gastric cavity. The overwork and ultimate exhaustion are the same in either case, but the pathology and therapeutics are a different question. In determining the exact regimen of dietetics in atonic dilatation, all symptoms and conditions must be subordinated to the one central

indication, namely, the restoration of the exhausted gastric muscle. In order to apply therapeutics specifically, the degree of exhaustion must be measured. He said the two main pathological conditions to be corrected in simple atonic dilatation of the stomach were the exhaustion of the gastric muscles and bacterial growth in the gastric cavity. The main effort must be directed against the muscle weakness, not only for the nutrition of the patient, but for the prevention of bacterial growth and the resulting toxins which produce many of the grave symptoms found in this serious malady. To correct the muscle weakness and allow the musculature to recover, it may be necessary to lessen the total amount of food for a period, and undernourish the patient, thus giving rest to the diseased organ at the expense of the whole organism. The gain here is twofold: First, food is better digested, and, second, it is not robbed of its nutritive value by bacterial growth. In the beginning of a course of dietetic treatment, after the stomach has been placed at complete rest, the question of the character, composition, preparation, and time of giving food presents itself. A uniform diet for all the degrees and forms of atonic dilatation cannot be arranged, but the author presented a few examples. Theoretically, a liquid diet is most advantageous; practically, finely divided solid food is best, properly prepared, with appropriate amount of liquid, sufficient to aid the stomach to macerate the mass and inject it into the intestines. Usually two meals a day are ordered, one in the morning and one in the evening. In connection with diet, certain mechanical methods of treatment are not only useful, but often indispensable. For the mechanical effect, lavage is recommended by most of the text-books, and added to this galvanic and faradic electricity, general baths, exercise and drugs. A large number of the patients he had treated in the last ten years had all these methods used without success, often with harmful results. He has presented many of this class of patients, after a course of treatment, before the Society, on several occasions. He has also shown the objections to lavage. It has its use in complete stagnation as a palliative measure. Those methods are most valuable which will mechanically affect the gastric muscles direct, without washing out the necessary nutriment and secretions from the stomach cavity. Riegel seems to have obtained but little benefit from the use of static, galvanic or faradic electricity. The speaker has found high frequency with the Oudin resonator of considerable benefit as an adjuvant.

Diet in Hyperchlorhydria.—Dr. B. W. Sippy, in a paper on this subject, said that hyperchlorhydria designates a condition in which an abnormally great quantity of hydrochloric acid is secreted during the time the food is in the stomach. The subjective symptoms of the condition are referable chiefly to the irritation produced by the excessive quantity of hydrochloric acid upon the nerve endings of the mucous membrane and stomach and the adjacent esophagus. The following symptoms are more or less distinctive: Gastric discomfort, appearing from one to two hours after eating, combined often with eructations of gas, a feeling of fulness, burning sensation in the stomach, heartburn, acid pyrosis, rarely nausea, and still more rarely, vomiting. Patients seriously afflicted restrict their diet because of fear of distress after eating; they lose weight, become irritable, and form by far the largest contingent of the chronic dyspeptics. Accuracy in diagnosis demands chemical analysis, which is simple. When hydrochloric acid is in excess to the normal, surplus symptoms may be present or not, depending largely upon the sensitiveness of the nerves of the gastric mucosa. Even a very high grade of hyperchlorhydria may produce no symptoms. Such a hyperchlorhydria is said to be latent. In some cases a hyperesthesia of the mucous membrane to normal acidity is present. Clinically, such cases are symptomatically hyperchlorhydrias, and are inseparably related to hyperchlorhydria as determined by chemical analysis. In the treatment of the condition diet is all-important; but etiology must be taken into account in each case. The following causes were mentioned: Hasty eating, improperly prepared food, overeating, certain ill-defined disorders of the nervous system are responsible in many cases. Frequent in neurasthenics; secretion may be increased or abnormal sensitiveness of the nerves may be induced by mental states, nervous shock, worry and fatigue. The anatomical causes that are operative are ulcer, with or without pylorus spasm. In the irritative stage of gastritis, hyperchlorhydria may be present. There may be benign pyloric obstruction. There are certain toxic causes, chiefly the abuse of alcohol and tobacco. Fortunately, by close attention to diet alone most cases may be satisfactorily treated. The diet should fulfill the following indications: First, mechanical, chemical and thermal irritation of sensory and secretory nerves of the stomach by food and drink must be reduced to the minimum. Second, food should contain a liberal quantity of albumin to combine with the excessive hydrochloric acid. Third, the diet must be sufficiently nourishing. Fulfilment of indications is simple. All foods should be taken in a state of fine subdivision, and great care given to thorough mastication. Meat should be scraped or finely teased apart. Potatoes and all vegetables should be given in as near puree form as possible. Pickles, potato salad, fried potatoes, coarse nuts, radishes and similar coarse articles should be avoided. Coffee, spices, sharp condiments, mustard, pepper, vinegar, acids, and alcoholic drinks should be avoided. Hot and cold food and drink should be avoided. The diet should be a mixed one, containing albumin, fat and carbohydrates. In the beginning of the treatment a liberal quantity of albumin in the form of lean meat should be given, because it is non-irritating and combines a maximum quantity of hydrochloric acid. Fat in the form of butter and cream is well tolerated, and tends to reduce the quantity of acid secreted. Because the excessive acidity quickly inhibits the action of the ptyalin, the starches should be restricted moderately at first or given in dextrinated form, as zwieback or toast. The following plan may be adopted in most cases with success: For a man weighing 160 pounds, during the first week or ten days one-third pound of rare steak, well cooked, veal, mutton, lamb, chicken or turkey; sixty grams of toast or zwieback, a glass of milk and cream, equal parts, an ounce of butter, and, if desired, a soft egg or a hard-boiled egg grated for each of the three meals a day. If constipation is present, stewed apples, prunes or figs may be added to the diet. As a rule, little discomfort, aside from a slight fulness, is experienced. A powder of calcined magnesia and sodium bicarbonate, equal parts, ʒss, may be given after meals, at the time discomfort appears. A gain of two and three pounds will usually be recorded during the first week. The diet is then enlarged. Rice, oatmeal, well-cooked; vegetables, puree, stale bread may gradually be substituted for toast, and after four or five weeks a normal diet may be resumed. The patient should be instructed to avoid certain named articles, and at the first intimation of

an attack the restricted diet should be resumed for a few days.

Dietetics in the Treatment of Diabetes.—Dr. A. C. Croftan limited his discussion to a disquisition on the modern mathematical ideas underlying the dietetic treatment of diabetes, and called attention to the fact that in the light of our latter-day knowledge of metabolism it is possible to regulate the diet of diabetic cases with absolute accuracy. He condemned the popular fallacy of withdrawing all carbohydrates from the food in every case that presents itself with sugar in the urine. The two chief dangers of this practice are, in the first place, the utter impossibility of adequately nourishing patients with fats and meats alone; in the second place, the danger of permitting the development of diabetic acidosis, and its almost inevitable consequence, diabetic coma. The speaker at some length explained the application of certain physical laws in regard to the heat and labor equivalents to physiological and pathological processes, and showed by simple calculation of the caloric value of the food and the caloric value of the excreted sugar, that one can determine mathematically just how much loss of proper tissue the patient suffers, and precisely which of the tissues are sacrificed. He recommended establishing several degrees of glycosuria: One in which the patients can tolerate a certain amount of carbohydrates; a second one, in which not only the carbohydrates must be withdrawn, but a certain proportion of the food albumin must be reduced before the sugar disappears; a third and most severe form, in which the sugar does not disappear, even when all the carbohydrates and a large proportion of the albumin are withdrawn. Based on this subdivision, the dietetic treatment must be regulated. In conclusion, the author spoke of the factors that determine the development of acidosis and coma, and mentioned the dietetic means to prevent these accidents. He bitterly condemned the shallow practice of handing patients with diabetes printed diet sheets at random, and made a strong plea for strict individualization in the treatment of this disease.

Dietetics in the Treatment of Brights Disease.—Dr. Arthur R. Elliott stated that the scope of this subject is so broad that no attempt was made to consider it in full detail. The speaker confined his discussion of the subject to a consideration of the most important recent advances in this field of research. The principles of protective dieting in Brights disease include not only relief to the kidney from all superfluous work and irritation, but also the no less important consideration, caring properly for the nutritive needs of the general economy. In order to enforce rationally these principles, it is necessary to know which of the urinary solids are easily excreted, and also those which are removed with difficulty by diseased kidneys, so that we may be in a position to exclude all foods that cause the formation of end products which are inimical to the kidneys. Von Noorden's studies of the excretion of metabolic products furnished the author with information that enabled him to construct such a dietary. He found that among substances excreted with difficulty in nephritis are urea, inorganic sulphates, creatinin, urine pigments, hippuric acid, phosphates, and, under certain circumstances, water. On the strength of these findings he excludes, on account of urea and inorganic sulphates which they contain, all proteid foods over and above the amount necessary for purposes of systemic nutrition. On account of creatinin, meat extracts and broths; on account of urine pigments, foods containing hemoglobin; on account of phosphates, he advises that calcium carbonate be given in medicinal doses several times daily, when the patient is taking milk freely in order to arrest the phosphoric acid in the bowel, when it remains in combination with calcium. On account of the hippuric acid which they contain, he excludes certain green vegetables, cranberries, and fruits containing kernels (prunes, plums, etc.). On account of uric acid and alloxin bodies, he excludes all glandular organs used as foods, *i.e.*, kidneys, liver, sweetbreads, also coffee and all malt beverages. Alcohol is also forbidden, save for medicinal purposes. Milk still remains the staple article of diet in acute nephritis. The more nearly the disease approximates the acute form, the more exclusively should milk be used as the chief source of proteids. Exception is taken to exclusive milk diet in acute nephritis, owing to the poverty in iron, and the large quantity (three to four liters) necessary to furnish the nutritive calories needful for systemic purposes. It is advised, therefore, to enlarge the milk regimen by the addition of simple farinaceous foods and modify the milk by the addition of sterile cream in the proportion of one to four of milk. Of this mixture, one and one-half to one and three-quarters liters a day is allowed the patients with acute nephritis. As convalescence progresses, the diet is gradually extended. Full normal diet should not be permitted until all signs of nephritis have disappeared in the urine. Exclusive milk diet is inapplicable to the treatment of chronic nephritis, owing to the nutritive deficiencies and unfavorable influence on pulse tension. Formerly patients were urged to drink abundant quantities of water under the mistaken idea that by such means elimination of organic waste was increased. As a matter of fact, during the stage of dropsy in acute nephritis water is one of the substances excreted with difficulty by the kidneys. Great benefit may follow the restriction of fluids during this stage. This course is especially indicated if dyspnea or other evidence of cardiac embarrassment exists. As the case improves, the fluids may be increased in amount. By controlling the amount of chlorides ingested with the food, Widal and Javal were able to demonstrate that in certain cases of parenchymatous nephritis edema and albuminuria could be markedly influenced. By excluding as far as possible all chlorides from the diet, a decided reduction of the dropsy and albuminuria was effected. They conclude that salt is for certain cases of parenchymatous nephritis a dangerous food constituent, and they propose a cure by dechlorination, *i.e.*, the exclusion of all salt from the diet. Their results have been confirmed by subsequent observers. The writer reports two cases of parenchymatous nephritis very favorably influenced by this treatment. It is probable that in the dechlorination principle we possess a valuable adjunct to the treatment of parenchymatous nephritis. Dietetics in chronic interstitial nephritis is much more involved than in other forms. The high arterial tension with cardiac hypertrophy almost invariably present introduces a peculiarly difficult element into the treatment of these cases. Any diet which does not take into account these cardiovascular conditions will prove inappropriate and harmful. Regarding the choice of proteids, it is now known that the old and oft reiterated dogma of the superiority of white over red meats is incorrect. The researches of Walker, Hall, and Kaufmann and Mohr prove that red meats are no more harmful than white, and are equally available to the nephritis invalid. The vegetarianism of some clinicians is to be condemned, on account of its bulk, nutritive deficiencies, and high content of water. Meats are conse-

quently a necessary part of the diet in this disease, and it is a matter of indifference whether white or red meat is taken. We must nevertheless strictly confine the amount of proteid food within certain fixed limits. The limit of renal capacity for nitrogen excretion in interstitial nephritis corresponds to the ingestion of about 100 grams of albumin. Within this limit the amount should be restricted. It should never be forgotten that every patient with interstitial nephritis also has heart disease, and that high tension and cardiac failure are constantly menacing elements. Consequently the simple rules of cardiac hygiene, of which moderate-sized meals and limitation of fluids are among the most important, must be enforced. Provided the amount of fluid be not reduced below 1,500 c.c., organic elimination via the kidneys is not interfered with. In the presence of stenocardia it may become necessary to abandon the habitual dietary, and temporarily substitute one specially designed for lower arterial tension. Restriction of fluids to the lowest limit compatible with comfort, and a diet of bread, fruit and nuts may accomplish this within a few days.

CANADA.

A New Secretary for the Ontario Board of Health.—The Ontario Government has appointed Dr. Charles A. Hodgetts to the position of secretary for the Provincial Board of Health, a position which was rendered vacant through the appointment of Dr. Peter H. Bryce as Medical Inspector of Immigration under the Dominion Government. Dr. Hodgetts has been connected with the Ontario Board of Health since 1890 and was appointed to the position of medical inspector permanently in 1900. The new secretary is a graduate of the Ontario College of Pharmacy (1878) and also a graduate of the Toronto School of Medicine and of Victoria University (1886). After graduation he was for a time house surgeon at the Toronto General Hospital, after which he studied for three years in English hospitals, where he took the degree of L.R.C.P., London. He has had charge of several smallpox outbreaks in the province

To Fight Tuberculosis in British Columbia.—A largely attended public meeting was held in Victoria, B. C., January 20, for the purpose of forming a provincial association to be called the British Columbia Association for the Prevention and Treatment of Tuberculosis. Dr. C. J. Fagan, secretary of the Provincial Board of Health, presented the question at considerable length and moved the resolution establishing the Association. He referred to the need of such an organization, as British Columbia was not abreast of the times in the respect of dealing with her tuberculous citizens, and then there were annually lost to the province 200 lives through consumption. He considered that Kamloops was an ideal spot for a sanitarium and stated that Mr. Gage, of Toronto, the treasurer of the National Sanitarium Association, had promised aid. Financial assistance will also be sought from the local government of the province as well as from the Federal Government. The Lieutenant-Governor, Sir Henri Joly, was elected Hon. President; Dr. Proctor, of Kamloops, secretary, and on the Executive, Dr. J. C Davie, of Victoria, and Dr. R. E. Walker, of New Westminster.

Annual Meetings of Medical Associations.—The Canadian Medical Association meets this year in Vancouver, B. C., under the Presidency of Dr. Simon J. Tunstall of that city. Dr. George Elliott, 129 John Street, Toronto, is the General Secretary. Mr. Mayo Robson will be a guest of the Association. The dates for the meeting are August 23-26, 1904. The Ontario Medical Association meets in Toronto on June 14-16, 1904, under the Presidency of Dr. James F. W. Ross, of that city. Dr. Chas. P. Lusk, 99 Bloor Street, West, is the General Secretary.

The Death of Dr. John Herbert Sangster.—A notable figure in the medical life of the province of Ontario passed away suddenly of heart disease on January 27, while a guest at the King Edward Hotel, Toronto, in the person of Dr. John Herbert Sangster, of Port Perry, Ontario. Dr. Sangster was seventy-two years of age and came to Canada from London, England, with his parents in 1831. From 1866 until 1871 he was principal of the Toronto Normal School, being at the same time Professor of Chemistry and Botany in the old Dr. Rolph's School of Medicine. At that time he completed the study of medicine, and upon his retirement from the principalship of the Normal School in 1871, he moved to Chicago, but shortly after returned to Canada, and commenced the practice of medicine at Port Perry, where he continued in active practice up to the time of his death. The late Dr. Sangster was a member of the Ontario Medical Council to which body he was elected in 1894. He immediately entered upon a campaign looking toward the exclusion from that body of the representatives of defunct teaching bodies. Many years ago Sangster's arithmetic was the standard text-book in the Ontario public schools. He was a frequent contributor to the public press, much more than he was to the medical press.

Experiments with Marmoreck's Tuberculosis Serum in Montreal.—Two patients at the Notre Dame Hospital, Montreal, have been recently injected with Marmoreck's serum, one with tuberculosis of the lungs and the other with tuberculosis of the knee-joint. The operations were made under the supervision of Dr. L. J. Lemieux, of Montreal, who has lately returned from Paris, and where, he states, he witnessed 25 cures for consumption by means of this serum treatment. Dr. Lemieux brought back with him serum sufficient for the treatment of 15 patients. This is the first time the serum has been employed in Canada, and probably the first used on this side of the Atlantic.

Personals.—Dr. T. J. Norman, of Toronto, has been appointed assistant superintendent of the Asylum for Feeble-Minded at Orillia, Ontario, to succeed Dr. Moher. Among the Canadians attending the Tuberculosis Exposition at Baltimore, last week, were Dr. J. George Adami, of Montreal, who contributed a paper on the "Facts, Half Truths and Truths about Tuberculosis," and Dr. J. H. Elliott, Medical Superintendent of the Muskoka Cottage Sanitorium, who presented interesting exhibits and models.

GENERAL.

National Legislation for Pure Food.—The Senate Committee on Manufactures, which last week made a favorable report on the McCumber Pure Food bill, will take up next week the Hepburn bill, which has already passed the House. The Hepburn bill provides that a drug shall be deemed to be adulterated if, when it is sold "under or by a name recognized in the United States Pharmacopœia, it differs from the standard of strength, quality, or purity, as determined by the test laid down in the United States Pharmacopœia, official at the time of the investigation." The McCumber bill tempers this provision to some degree by inserting the proviso "that no drug shall be deemed to be adulterated under this provision if the standard of strength, quality, or purity be plainly stated upon the bottle, box, or other container thereof, although such standard may differ from that determined by the test laid

down in the United States Pharmacopœia. In the further provisions regarding the adulteration and misbranding of foods and drugs the McCumber bill takes the specific definition found in the Hepburn bill, as, for example, "if any valuable constituent of the article has been wholly or in part abstracted," and adds to each such clause the words "so that the product when sold or offered for sale shall deceive or tend to deceive the purchaser." The distinction made by the additional words is a very slight one, and its effect on the enforcement of the law would be for the courts to determine. It is easy to imagine a case in which, for instance, a "substance or substances has or have been substituted wholly or in part for the article," when there would be no deceit. Suppose that for one of the ingredients of a prepared mustard a red substance had been added, making the whole product of a dark orange color. The purchaser would hardly be deceived, as it would be perfectly plain that some substance not in the ordinary formula had been added. Such a product would apparently be deemed adulterated under the Hepburn bill, but not under the McCumber bill.

Medical Library for Maryland.—At a meeting of the Medical and Chirurgical Faculty, held December 28, 1903, it was unanimously resolved to make an appeal to the legislature for an appropriation of $100,000 for the purpose of erecting a suitable and fire-proof building to contain the great medical library which for the last fifty years has been collected by our association, which has become one of the most complete and valuable libraries in this country, and which has now outgrown its present cramped quarters. The grounds upon which they base their appeal are as follows: (1) That the Medical and Chirurgical Faculty, which represents the medical profession of the City and State, have with great effort collected during the course of many years, a valuable medical library, one of the most complete medical libraries in this country; that this library has outgrown the quarters which the profession purchased out of their own collections and with great difficulty; that the destruction of this library by fire would be irremediable, and would be a loss to the entire people as well as to the profession; and finally that the resources of the medical profession are insufficient for the erection of a suitable building. (2) That it is well known that the medical profession, both directly and indirectly, serves the State and the public without remuneration, in advice in matters hygienic, in efforts to improve the health and well-being of the citizens, and in preventing the spread of disease. And that for these reasons, the medical profession deserves the assistance of the State in the effort to place the central library, one of its most powerful instruments, in a proper and adequate building, where it will be protected against destruction and where it may steadily grow. (3) That in providing for the medical library, the State will not only benefit the profession, but by giving the profession the means to improve itself, to study the old and to inform itself of the new discoveries of medical science, as well as to stimulate further research and observation, it will serve itself, for the real benefit will accrue to the citizens themselves; that Maryland is fast becoming one of the leading States in advancing medical science, and that this reputation is of great value to the State; that the improvement of public hygiene, for which the City of Baltimore and the State annually expend great sums of money, as well as the numerous public hospitals and asylums, which depend entirely, or in great part, upon the State and City's treasury, and over which the State and the City of Baltimore act as guardians, require as an absolute necessity the preservation and the continued growth of this great library. (4) That this library is not only of service to the members of the Medical and Chirurgical Faculty, but that access is possible to any member of the profession and to the thousands of medical students who are attracted to Baltimore from every part of the United States and from distant countries. (5) And last of all, this Faculty, which has been for more than 100 years the guardian of public health, the incentive to improvement in its own members and in the entire profession of the State, has never before applied to the legislature for financial aid for any purpose. To accomplish our purpose, it will be necessary for each and every member of the city and county societies to take an active interest, and to personally interview and request the representatives in the legislature (both Senate and House) to support the measure themselves, and to use their influence upon their associates to have this bill favorably acted upon.

Recent Statistics of Physicians.—*The United States.*—The total number of physicians in the United States is probably about 105,000, that of regular practitioners being about 95,000. During 1902 the deaths of 1,400 regular practitioners of the United States were recorded in the *Journal of the American Medical Association.* This is probably within 5 per cent. of the total mortality in the profession of the United States. Consequently the death-rate for the year was about 14.74 per 1,000, a lower rate than is usually supposed to obtain in the profession. The statistics of American life insurance companies show a mortality-rate per 1,000 among physicians of 7 at the age of 25, 15 at the age of 35, 21 at the age of 45, 34 at the age of 55, and 112 at the age of 65. The statistics of the United States census of 1900 show figures closely parallel with the estimate given by the *Journal. Canada.—The Canadian Journal of Medicine and Surgery* compares the situation of the medical profession in France to that of the profession in Ontario. The comparison is significant. In the rural districts of France there are about 3 doctors per 10,000 of population. In the larger cities there are 7.4 per 10,000, and in Paris 10.65 per 10,000. Throughout Ontario there are 11.4 doctors per 10,000, while in the city of Toronto the physicians number 20 to the 10,000. Roughly speaking, therefore, there is in Ontario double the number of physicians per head of population that there is in professionally overcrowded France. *Germany.—Dr. Weimer's Medical Directory* states that there are now 28,127 medical men in Germany, as compared with 27,039 in the previous year, 26,470 in 1900, 26,049 in 1899, 25,178 in 1898, and 24,393 in 1897. The increase of 1,088 in the number of medical men from the year 1901 to the year 1902, is an increase of 4 per cent. and is greater than in any previous year. During the past five years the numerical increase of the medical profession was 3,734, or 15.2 per cent., while the increase of the general population was 9.3 per cent. As regards distribution throughout the various States it is found that 17,126 medical men reside in Prussia, 2,790 in Bavaria, 2,148 in Saxony, 1,147 in Baden, 937 in Würtemberg, 814 in Alsace-Lorraine, and the remainder in the smaller States of the Empire. There are 2,366 medical men in Berlin, 583 in Munich, 573 in Hamburg, 548 in Breslau, 433 in Dresden, 431 in Leipsic, 344 in Cologne, 354 in Charlottenburg, 338 in Frankfort, and 304 in Königsberg. *Austria.*—The Austria *Medizinalkalender* for 1903 states that the number of medical men at the end of 1902 was 11,339. At the corresponding period of the previous year it was 10,797. They are distributed as follows: Lower Austria, 3,325; Upper Austria, 393; Salzburg, 124; Styria, 675; Carinthia, 148; Krain, 104; Küstenland, 330; Tyrol and Vorarlberg, 601; Bohemia, 2,789; Mähren, 943; Silesia, 237; Galicia,

1,382; Bukowina, 130; Dalmatia, 140. In Bosnia Herzegovina there were 100 practitioners. Taking the chief cities, in Vienna there were 2,576 practitioners; in Linz, 60; in Salzburg, 40; in Graz, 270; in Klagenfurt, 37; in Laibach, 36; in Trieste, 181; in Innsbruck, 84; in Prague, 538; in Brunn, 188; in Troppau, 37; in Lemberg, 288; in Czernovitz, 57, and in Zara, 17. *Finland.*—According to official statistics which have recently been published, there are in Finland 414 legally qualified medical practitioners. This does not include 25 medical officers of the Russian garrison. There are 31 dentists. The number of unqualified practitioners is given as 14, so that Finland would seem to be in the happy position of being almost free from quacks.—*Medical Book News.*

Study of Infectious Diseases in the Philippines.—Drs. E. L. Tyzer and W. R. Brinkerhoff, who have been assisting Dr. W. T. Councilman, of Harvard University, in recent experiments into the causes of smallpox, will leave for Manila at once, to continue work there along the lines pursued at Harvard. Funds for the undertaking have been provided by popular subscription, and it is planned that the two doctors shall remain a year. Other tropical diseases, which are likely to be brought to this land through growing intercourse with the islands, will be considered also, with a view of preparing American physicians for their treatment.

Disinfection for German Libraries.—The Berlin municipal authorities have decided to make an attempt to exterminate the microbes in the public libraries, Prof. Koch having called attention to the danger of spreading infectious diseases through books loaned indiscriminately from libraries. A plan for attacking the microbes will be submitted to the Library Committee of the Municipal Council on Feb. 2. It is intended to adopt some method of disinfecting books after their use.

Pharmacologist.—The United States Civil Service Commission announces an examination on March 1, 1904, to secure eligibles from which to make certification to fill a vacancy in the position of pharmacologist (male) in the Bureau of Plant Industry, Department of Agriculture, at $1,800 per annum, and other similar vacancies as they may occur. Applicants will not be assembled for this examination. The person appointed to this position must be a man trained and equipped with the knowledge and experience necessary for isolating and handling poisonous and other active principles of plant origin. He must be trained in animal physiology and pharmacology, and must have had experience in studying by exact laboratory methods the effect exerted on the different animal functions by the active principles of plant origin. He should be familiar with the best forms of apparatus used in carrying on such experiments and should have abundant laboratory experience in making such investigations. He should be able to read at least French and German, in addition to English. Age limit, twenty years or over. This examination is open to all citizens of the United States who comply with the requirements. Competitors will be rated without regard to any consideration other than the qualifications shown in their examination papers, and eligibles will be certified strictly in accordance with the civil service law and rules. Persons who desire to compete should at once apply to the United States Civil Service Commission, Washington, D. C., for application Form 1312, which should be properly executed and filed with the Commission at Washington, with the material required, prior to the hour of closing business on March 1, 1904. In applying for this examination the exact title as given at the head of this announcement should be used in the application.

The Maryland Tuberculosis Congress.—Some alarming facts are brought home to Baltimoreans at the tuberculosis exposition, which opened last week in McCoy Hall, under the auspices of the Tuberculosis Commission of Maryland, conjointly with the State Board of Health of Maryland and the Maryland Public Health Association. If the observations of the health officials are correct, the pavements around Baltimore's City Hall and Courthouse are among the filthiest in the city, and the street cars are about as dirty as those to be found anywhere. The "City Hall Sputistics" are something that catches the eye of the visitor soon after entering the exposition. A reading of the chart is calculated to make a Baltimorean fairly blush when he remembers that the city has an anti-spitting law and the manner in which it is enforced. The "Courthouse Sputistics" are hung near those of the City Hall. Here is what is said of the City Hall pavements: In eight walks around the City Hall on eight different days, between the hours of 10 A.M. and 2 P.M., there were counted: Separate deposits of sputum—2013. Highest count was made on January 16, 1904—390. Lowest count was made on December 26, 1903 (bitter cold)—144. Average count—251.6. Filthiest spot—Holliday street front. In second degree disgusting—honor divided between southeast and southwest corners. And then this chart, on which is pasted a photograph of the new courthouse: In nine walks around the Courthouse on nine different days between the hours of 10 A.M. and 2 P.M., there were counted: Separate deposits of sputum—3,793. Highest count, on December 31, 1903—560. Lowest count, on December 26, 1903 (a bitter cold day)—235. Average—421.5. Filthiest spot—St. Paul street entrance. In the second degree disgusting—Calvert street entrance. Another chart at the Exposition refers to street cars in Baltimore. This information was also gathered by Drs. Fulton and Price, and the observations are to the effect that the motormen and conductors are among the biggest violators of the anti-spitting law. It reads as follows: Street-Car "Sputistics." 248 car rides; 3,156 passengers; 944 separate deposits of sputa; 4 sputa per car; 41 crowded cars; 125 counted deposits; 3 sputa per crowded car; 49 wet cars; 52 counted sputa on wet cars; 1 sputum per car; 90 cars crowded or wet; 177 counted sputa; 2 sputa on crowded or wet cars; 158 cars neither crowded nor wet; 817 separate deposits; 5.17 per car; 30 times spitting witnesses; 2 conductors seen to spit on cars; 5 motormen seen to spit on cars; pools are counted as on deposit; motormen are depositors of pools.

Gov. Edwin Warfield made the opening address, and among the others who spoke were Mayor McLane, Dr. William Osler and Mr. Frederick Hoffman of Newark, N. J. All urged upon the audience the necessity of taking steps to prevent the spread of tuberculosis, and advised all to visit the exposition. Dr. Lawrence F. Flick, of Philadelphia, lectured on "House Infection of Tuberculosis." Dr. Mazyck P. Ravenel, of Philadelphia, read a paper on "Bovine Tuberculosis a Factor in Human Tuberculosis." Dr. D. E. Salmon of Washington, spoke on "Some Observations on the Tuberculosis of America." The tent exhibit was among the most interesting in the hall. It showed a number of tents used by physicians in different parts of the country in treating their patients, and one was a model of the tents on Ward Island, used by the consumptives of New York, and made especially for the exposition by the patients. The Congress was a great success.

The History of Consumption.—Dr. William Osler addressed the final meeting of the Tuberculosis Exposition. The big auditorium in McCoy Hall was filled to the doors with ladies, students, physicians and lay-

men to hear "The History of Tuberculosis." He began with Hippocrates, the father of medicine, as he is commonly known, and came on down to modern times, with biographical, critical and explanatory comments. The Greeks, he said, knew of the disease, but were unable to treat it, for they did not know its cause. Galen, Dr. Osler said, was the first to recommend open-air life for consumptives as a means of recovery. The Romans early took advantage of this, for it is well known that they used to send their tuberculosis sick on long sea voyages to Egypt. Celsus was another great advocate of out-of-door habitation. Turning to France, Dr. Osler spoke particularly of Lænnec, the inventor of the stethoscope. Dr. Osler told some amusing anecdotes about Lænnec, who went to Paris early in life and there became a student of medicine. His great book on the discovery of the stethoscope was published about 1819. He is responsible for the theory of the unity of tuberculosis; that is, that the disease in all its forms has a common origin. Willeman, Dr. Osler said, was the first to prove by bovine inoculations that tuberculosis passes from man to cattle and from cattle to man. Then the great Koch, with his elaboration of this idea, was taken up. Dr. Osler passed around several valuable and rare volumes and, in closing, said: "Probably it would be too much to hope to get rid of tuberculosis entirely. But it has been unmistakably shown that it can be prevented, and some day—who can say?—there may be a way of guarding against it by vaccination. This means in a crude way has been tried on calves with some success. The best we can do is to use fully the means we can command for combating the disease, such as getting control of tenements and sweatshops, teaching cleanliness and care and enforcing laws of sanitation.

OBITUARY.

Dr. PHOEBE JANE BABCOCK WAIT died at her home, in New York, last week. She was born at Potter Hill, R. I., Sept. 30, 1838, and acquired her early education in the district schools, in which she was afterward a teacher. Later she entered Alfred University, receiving from it the degree of Bachelor of Arts and of Master of Arts. Subsequently she came to this city, and in 1863 was married to William B. Wait, Principal of the New York Institution for the Blind, who survives her. Entering upon the study of medicine in 1868, when women in that branch of science met with violent opposition, she became a student in the New York Medical College and Hospital for Women, and was graduated in 1871. Immediately upon her graduation she entered upon active practice, devoting a large part of her practice to the study of obstetrics. In 1880 she was elected to be Professor of Obstetrics in the New York Medical College and Hospital for Women, which chair she held for upward of twelve years, during part of which time she was also Dean of the college. In 1879 she received the diploma of the New York Ophthalmic Hospital and College.

Dr. GEORGE H. R. BENNET died of apoplexy at his home, 21 South Portland avenue, Brooklyn, on January 26, in the sixty-seventh year of his age. Dr. Bennet was the son of an old Brooklyn physician and was born in Brooklyn. He was graduated from the medical school of the New York University in 1860. He was a member of various local medical societies, the Brooklyn Medical Club and the Crescent Athletic Club, and at one time served as surgeon of the Twenty-third Regiment.

Dr. GEORGE THOMPSON died last Tuesday from old age. He was born in Belfast, Ireland, in 1817. He practised medicine in this city for forty years, most of the time in East Twentieth street. He gave up active work fifteen years ago.

CORRESPONDENCE.

OUR LONDON LETTER.

(From Our Special Correspondent.)

LONDON, January 16.

THE CENTRALIZATION OF MEDICAL TEACHING IN LONDON—AN INTER-HOSPITAL WAR—THE LONDON POLYCLINIC—TUBERCULOSIS IN THE POSTAL SERVICE—THE PATHOLOGY OF CHRONIC ALCOHOLISM—PROGRESS OF CREMATION.

REFERENCE has been made in previous letters to the proposal to centralize the teaching of anatomy, physiology and the other sciences which form the foundations of medicine which at present are taught more or less efficiently in the twelve independent medical schools in which this metropolis rejoices. The scheme is taking practical shape, and already negotiations for the purchase of a suitable site are in progress. Unfortunately it seems to be considered necessary that the site of the proposed Institute of Medical Sciences should be in the near neighborhood of the existing local habitation of the University of London. This means that it will have to be found in South Kensington, one of the most expensive quarters in London. Not only will land be of great price there, but it will be difficult for students, who are not as a rule richly endowed with worldly goods, to find suitable lodgings within reasonable distance of the Institute. It is proposed that premises and equipment adequate for the instruction of 500 students in anatomy, physiology (including pharmacology), biology (zoology and botany), chemistry and physics should be provided. The total cost of the buildings is put at $800,000, while it is estimated that an annual expenditure of $102,500 for teaching will be necessary. Toward all this little or nothing has so far been subscribed by the public to whom a strong appeal was made not long ago by Lord Rosebery, Chancellor of the University, and the other principal officials of the University. It is almost hopeless to ask a British Government for substantial help in furtherance of such a scheme, and for some reason or another millionaires do not appear to find a stimulus to generosity—or self-advertisement—in the University of London. Yet there are here the makings of a university—particularly in the department of medicine—such as the world has hardly yet seen. The fact is, I believe, that there has been so much squabbling about trivialities and so much jealousy and narrow-mindedness among those who undertook the reconstitution of the University of London that people are disgusted with the whole thing. The struggle has been going on for nearly a score of years and is not yet finished. But it really seems as if the obstructives were about to be beaten all along the line, and London at last to have a living teaching university instead of a system of examining boards.

A triangular duel is now being carried on between St. Bartholomew's, King's College and the London hospitals. All three institutions want money badly, and each is angry with the other for asking help from the public. St. Bartholomew's is the oldest hospital in London, its foundation dating from the twelfth century. It is also the richest, having a revenue of half a million dollars a year. The other hospitals therefore profess great indignation that so wealthy an institution should stoop to send round the hat, and "queer their pitch," to use the language of other members of the mendicant fraternity. The authorities of King's College Hospital not long ago, intimated to those of St. Bartholomew's that if they persisted in the appeal they would do their utmost to spoil their chance. Last summer the London Hospital strained every nerve to forestall St. Bartholomew's in its attack on the public purse. All this is unedifying and likely to be detrimental to London

hospitals generally. St. Bartholomew's wants a trifle of $2,500,000 to rebuild the whole hospital, which is antiquated and inadequate to modern requirements. King's College Hospital wants a vast sum to enable it to migrate to South London where it is thought it will be more useful. It is very doubtful whether in either case the money will be forthcoming. Part of the opposition to the St. Bartholomew's scheme comes from one of our "yellow" journals, the *Daily Mail*, which, rightly or wrongly, is supposed to derive its inspiration from Sir Henry Burdette who poses here as the supreme and infallible authority on everything relating to hospitals. However this may be, someone who finds a mouthpiece in the *Mail* evidently wishes that the hospital should cease to exist, and be replaced by two smaller institutions in the country. I cannot think, however, that in a country so conservative of ancient institutions, so venerable a foundation will be allowed to perish. The medical staff—a body consisting of twenty-six of the most prominent members of the profession in London—are unanimous in urging that the hospital should be rebuilt on its present site, and the governors, after a good deal of persuasion, have virtually agreed to this course. A meeting is to be held on January 26 under the presidency of the Lord Mayor to arrange a plan of campaign for the purpose of raising the money required.

The London Polyclinic which owes its existence largely to the energy of Mr. Jonathan Hutchinson, is also in want of money. It has hitherto been mainly a place for the housing of specimens and pictures of out of the way diseases collected by Mr. Hutchinson, and for the demonstration of remarkable cases by that comprehensive specialist. It also published a journal which was practically an organ by means of which he kept the world enlightened as to his views on leprosy. The intellectual diet which he offered was good in its way, but it was not sufficiently varied for the average human digestion, and after a certain time surfeit necessarily followed. As in ancient times men got tired of hearing Aristides called the just, so here people have become weary of hearing the eminent surgeon speaking of himself. This of course is not the cause of the financial embarrassment of the institution that is officially put forward. Whatever be the explanation, it is a fact that the Polyclinic has failed to "draw," and its journal was a white elephant which cost it some three or four thousand dollars a year. Endeavors were made to get rid of this expensive luxury, but Mr. Hutchinson, who financed the institution, threatened to put up the shutters if this were done. To speak plainly, he has been to the Polyclinic like the Old Man of the Sea on the shoulders of Sinbad. On this account several of the men who took the most active part in starting it retired. The financial crisis became so acute a few months ago that the journal was discontinued. Now a *modus vivendi* seems to have been established. The journal has reappeared but in a much more modest form, and with considerable mitigation of the Hutchinsonian element. An appeal is made to the public for contributions and to the profession for a larger measure of support than it has hitherto given. The institution is unquestionably a useful one, but the truth is, it is not altogether popular with the profession. The hospitals look upon it as competing with them for cases, and the lectures have for the most part not been particularly attractive to general practitioners. If it should prove that the influences which have hitherto tended to paralyze its efficiency have ceased to be operative, the Polyclinic may yet have before it a career of great usefulness and prosperity.

For several years past efforts have been made to get the Postmaster General to take steps for the repression or mitigation of tuberculosis, which is assuming the proportions of a veritable scourge among the employees of the department. The staff in 1899 numbered 82,172, and in that year there were 62 deaths and 83 retirements due to consumption—a total loss of 145 persons. To-day the staff numbers over 179,000 and the incidence rate of phthisis among them has certainly not diminished; it may fairly be inferred, therefore, that from 300 to 350 persons yearly fall victims to the disease. It is naturally the indoor staff that suffers most; among them it is estimated that the loss must be at least 2 per 1,000 per annum. The amount of sickness may be reckoned at 4 per 1,000. To appreciate the significance of these figures it must be remembered that before admission all candidates must pass a strict medical examination. Yet the mortality among those selected lives is considerably higher than among equal numbers of people taken at random. The heads of the department have shown the usual apathy of officials in regard to the matter. Their attention was drawn to the prevalence of consumption among their employees some eight years ago. It was not till two years later that even the small step was taken of prohibiting spitting in the buildings of the department. Last year, after repeated representations had been made, orders were issued that war was to be made on dust and proper means of ventilation provided. This order, being the outcome of imperfect conviction on the part of its framers, was carried out in a most perfunctory manner. All post-office work is necessarily dusty, and the dust has never been really got rid of. Walls were treated by a dry cleaning process which simply removed the dust from one place to another; at the Central Office all the cleaning of walls and floors is done in the presence of the staff, who have thus a largely increased chance of inhaling the germ-laden dust. The mail bags, coming from all parts of the world—sometimes through infected areas,—gather dust of all kinds on their way and are never disinfected. The ordinance against spitting was practically ignored. In short, no proper precautions have ever been taken, and a part of the Central Office is called by the staff the "Cave of the Troglodytes," owing to its darkness and its want of ventilation. Some 300 persons work there in artificial light all day long and numbers of them have to be removed owing to the injury done to their health. Many of the provincial post offices are as bad or even worse. The evil is so grievous that the employes have now determined to erect sanatoria for themselves. They hope to obtain some help from the Postmaster-General, but they know how difficult it is to induce those in charge of the public money in this country to loosen their purse strings and they are prepared to do without assistance from the State. It will be a disgrace to the Government if such a state of things in one of its great departments is allowed to continue without any attempt at redress.

On January 12, Dr. Ford Robertson, Pathologist to the Scottish Asylums opened a discussion at the Society for the Study of Inebriety on the pathology of chronic alcoholism. He said that the experimental investigations of various workers had clearly shown that chronic alcohol poisoning had a very harmful action on the defensive mechanism of the body. In addition to the weakening of the general immunity, there was an impairment of the local defences, especially in the upper portion of the alimentary tract, by the direct action of the alcohol. The chronic catarrhal changes, at first due to the action of the alcohol, became intensified by bacterial action, and a condition of chronic toxic infection from the alimentary tract was gradually established. Consequently the individual gradually developed various other disorders, located in accordance with his pow-

ers of resistance and various accidental circumstances. With regard to the inimical action of alcohol on the race, Dr. Robertson maintained that in this country alcohol was at the present moment one of the most potent causes of genetic variation, as it was unquestionably of somatic variation, and that the incidence of disease dependent upon defective resisting power on the part of the individual was thereby enormously increased. If these views were in accord with the facts, it was plainly the duty of a nation to do everything in its power to remove from its environments every inimical condition to which there was imperfect adaptation. He entirely dissented from the doctrines of the Archdall Reid School in regard to the importance of "alcohol and disease" as causes of human evolution.

The prejudice against cremation is yielding slowly but steadily. Nine crematories are at present at work in England—at Woking, Golder's-green, Manchester, Glasgow, Liverpool, Hull, Darlington, Leicester and Birmingham. One is being erected at Ilford, and others are proposed in St. Pancras, and at Bradford and Newcastle. On an average 500 cremations have taken place in Great Britain yearly—about three hundred in London, and two hundred in the provinces. Ireland has not yet adopted the system, and the Cremation Act of last year does not apply to that country. Hull was the first city in this country to possess a municipal crematorium, and it was also the first place where such a building was erected in a cemetery. The idea of the advocates of cremation was to have all crematoria in churchyards. Strong opposition to this course was taken by some of the English bishops, but sanction has been given to the erection in the cemetery of the new crematorium at Ilford.

REGARDING THE OWNERSHIP OF THE NAME VALENTINE.

To the Editor of the MEDICAL NEWS:

DEAR SIR: A concern, styling itself the A. S. Valentine Chemical Company, recently sprung into existence, is advertising a preparation in the form of a capsule for which it claims scientific and wonderful value in the treatment of gonorrhea, its complications and sequelæ.

Investigation shows that: This A. S. Valentine Chemical Company is a corporation formed under the laws of the State of New Jersey, and that its incorporators are A. F. Evans, Frank L. Shelton and Nannie L. Shouse, all residents of Kansas City, Mo. This company has a small office at a pretentious address in New York City, which address it uses in its advertisements.

The alleged "literature" offered in these advertisements consists of some extraordinary assertions, contains no records of scientific investigation, no clinical reports and no signatures of physicians.

The capsule they sell is a gelatine-coated thick fluid, bearing the name "Benzol-Capsule Valentine." The contents of the capsule have been represented as "distilled and encapsuled by Valentine's special process."

As is admitted by the person in charge of the office, who is one of the directors, no person by the name of Valentine has ever been connected with the A. S. Valentine Chemical Company, nor has any person with this surname given it his or her consent to the use of this name.

Whatever may have influenced this concern to select the name Valentine as a part of its corporate name, the fact that Valentine is my name, and that I, by my writings, have brought this name prominently before the Medical Profession in connection with the study and treatment of gonorrhea, and kindred diseases, makes it incumbent upon me to prevent, as far as lies in my power, any deception of the Profession and the public by the misuse of my surname. It would be an injustice to my colleagues and to myself were I, by silence, to lend credence to the inference their advertising obviously suggests. In order, therefore, to protect the Profession, the laity and myself, I hereby beg to call attention to the following facts:

1. That I have, in all my writings on gonorrhea, its complications and sequelæ, emphatically expressed my conviction that no drug or combination of drugs administered internally can be a specific in the treatment of these diseases.

2. That no drug or combination of drugs given by the mouth can destroy gonococci.

3. That I do not know the contents of the capsules sold by these people, and that I certainly do not recommend them or any other secret preparation.

4. That neither I, nor any relative, nor any acquaintance of mine, is in any manner connected with the A. S. Valentine Chemical Company.

5. That on January 7, 1904, through my legal adviser, Henry C. Quinby, Esq., of this city, I formally requested the A. S. Valentine Chemical Company to desist from the use of the name Valentine, and upon their refusal I caused a petition for an injunction against their so doing to be prepared for filing in the Circuit Court of the United States.

On January 20, the counselor of the so-called Valentine Company had an interview with my legal adviser, Mr. Quinby, which resulted in the former unequivocally advising his clients to cease using the word Valentine in any manner whatever.

I will thank any of my colleagues to inform me of any violation of this promise, so that I may, for the sake of the public, the Profession, and my own sake, prosecute as vigorously as the best possible counsel and any sum of money can. Most respectfully,

FERD C. VALENTINE.

New York, Feb. 1, 1904.

THE PATHOLOGICAL EXHIBIT AT THE TUBERCULOSIS EXPOSITION, BALTIMORE.

To the Editor of the MEDICAL NEWS:

DEAR SIR: Probably the most significant, if not the most interesting, fact connected with the Tuberculosis Exposition held at the Johns Hopkins University from January 25 to February 1 was the remarkable interest shown by the public generally, especially the ladies, in viewing and studying the pathological exhibit.

This part of the exhibit was held in a room devoted exclusively to it, and contained wax models from the Hôpital Saint Louis, Paris; the Surgeon-General's Museum, Washington; the Chicago Health Department; Agricultural Department, Washington; Boston Health Department, Dr. Theobald Smith; University of Pennsylvania, Dr. Ravenel; Adirondacks Sanitarium Laboratory, Dr. Trudeau; Biochemic Laboratory, Washington, Dr. De Schweinitz; Columbian University, Dr. Salmon; College of Physicians and Surgeons, Baltimore, Drs. Stokes and L. K. Hirshberg; Johns Hopkins Medical School, Drs. Welch and McCallum.

It is estimated that fully thirty thousand persons, not including physicians and students, viewed this part of the exposition, most of them being ladies. The original intention was only to permit physicians and students in the pathological museum, but the public generally took the room by assault, and it was necessary to have a constant corps of demonstrators present to make the exhibit intelligible and bring its lesson home to the lay mind. On one day, Saturday, fully seven thousand per-

sons must have visited this room, as estimated by the writer, who was demonstrating there. Not more than five per cent. of these were students, not more than fifteen per cent. were men.

The exhibit of tubercle bacilli in culture tubes, the process of making tuberculin, the dead bacilli stained under the microscopes, and Dr. Trudeau's latest method of immunizing rabbits interested the spectators most. These things seem to have a more dramatic appeal to laymen than we, as physicians, ever realize. The questions asked, and the general interest evidenced, made it difficult at times to keep the crowds moving on in order to make room for others.

There were about eighty species and varieties of living tubercle bacilli shown upon many different kinds of media, including sheep's serum glycerin, glycerin bouillon, glycerin agar, glycerin gelatin, glycerin egg albumin, Dr. Salmon's new media, human blood serum glycerin, etc. The best of these were sent by Dr. Theobald Smith, Dr. Ravenel and Drs. De Schweinitz and Salmon. Perhaps the culture which attracted most attention was a lineal descendant of Koch's original culture made in 1882. This was transplanted by Dr. Trudeau, and unfortunately before the exhibit closed, became contaminated with a penicillium fungus, due, no doubt, to the shaking up it sustained.

The most complete exhibit of dried, powdered, emulsified, glycogen extracted bodies of the bacilli, tuberculinic acid, copper tuberculinate, tuberculin O and R, were shown by Dr. Trudeau.

About fifty accurately reproduced drawings of photomicrographs of all stages and examples of tuberculous conditions, very much enlarged, were hung about the walls of the room. These skilfully made drawings were made by Dr. Charles Potter, one of the Johns Hopkins Hospital artists.

The pathological conditions were shown grossly by a most complete series from the museum of the Johns Hopkins and Physicians and Surgeons' laboratories. These included about fifty-odd specimens of pulmonary tuberculosis in all stages, apical, miliary, caseous, cavernous, fibro-caseous calcareous, healed and bronchoglandular.

Scrofulous glands in all stages, both human and herbivorous. From fifteen to thirty specimens showed tuberculosis of the larynx. Several conditions of tuberculous pleurisy in cattle and human beings were shown. Miliary, conglomerate and solitary tuberculosis of the spleen and of the liver in Kaiserling's solution showed the original autopsy colors.

Three very rare examples of miliary and fused tubercles along the thoracic ducts were prominent in the exhibit. There were possibly ten or twelve jars each containing Kaiserling preparations of tuberculous pericarditis. Because of the publicity, the specimens of tuberculosis of the epididymis and ovaries were only shown privately. Bovine and human tuberculosis of the kidneys in various stages, one calcareous, together with tuberculous conditions of the ureters and bladder were presented. Tabes mesenterica and a perfect example of miliary tuberculosis of the omentum were much commented upon, especially a jar showing the large pendulous variety of tuberculous peritonitis. Miliary tubercles over the peritoneum were seen—probably ten different preparations, one of them sent by the University of Maryland.

Tuberculosis of the intestines was completely and clearly demonstrated by various ulcerated parts. One long stretch of intestine showing only two ulcers, one of which had perforated through the gut, causing death by a general peritonitis, another showing about two hundred shallow ulcers in a portion only 25 cm. long. Tuberculous appendicitis, colitis and duodenitis were all there. Two samples of solitary tubercles in the adrenal glands were interesting, one of which had not produced Addison's condition. Tuberculous spinal and cerebral meningitis; caseation in the basal ganglia of the brain, and another case showing a large mass of caseation in the cerebellum were representative of cerebral tuberculosis. Tuberculosis of the bones were shown by three preparations of resected white swellings of the knee-joint, hip-joint disease, six caries of the vertebræ, several at the eleventh and twelfth thoracic. Osteomyelitis of the sternum, caries of the inframaxillary bone.

The wax models from the Surgeon-General's Museum were representative more particularly of tuberculous skin conditions. Lupus in almost every stage and upon every part of the body was visible. Palms of the hands, soles of the feet, ankle, leg, arm, neck, face, cheeks, nose, lips, were all reproduced in these wax models, with life-like appearance. One interesting set of models showed the lips and nose much involved in one, and in another showed complete restoration of the parts by the ultra-violet rays after a long course of treatment.

LEONARD K. HIRSCHBERG.

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Ninety-eighth Annual Meeting held at Albany, January 26, 27 and 28, 1904.

(Continued from Page 238.)

SECOND DAY—JANUARY 27TH.

The Submerged Tonsil.—Dr. Thomas Harris, of New York, spoke of the symptoms dependent upon the covered condition of the tonsil seen in certain persons in which the pillars of the fauces have united over it. Under these circumstances chronic infections are not unusual, as the function of the tonsil is to protect the throat from the microorganisms which inevitably find their way into the mouth, and the tonsil is unable properly to perform its function. The individuals with submerged tonsils are more likely to suffer from sore throats and various other infections in the back of the mouth and in the fauces than are those whose tonsils are in normal condition. He suggests therefore the use of a tonsil punch for the purpose of setting such tonsils free and enabling them to carry on their proper function.

Chronic Laryngitis.—Dr. Z. L. Leonard, of New York City, gave some illustrative cases showing the tendencies of certain individuals to suffer from chronic laryngitis. When this affection is common, respiration is not carried on as it should be and as a consequence infections of the lower pulmonary tract are likely to follow. Such patients are especially likely to contract tuberculosis and this fact must be constantly borne in mind and treatment must be as careful as possible in order to prevent such an undesirable result. Patients are very apt to consider their condition as not very serious and its gravity must be made very plain to them, since it is well known now that the tubercle bacillus is very commonly to be met with in our large cities and unless respiration is nearly normal, tuberculous infections are sure to take place.

Suppurative Otitis Media.—Dr. J. F. McCaw, of Watertown, N. Y., said that it is surprising how many physicians fail to appreciate the significance of a discharge from the ear. How often, when parents come to the otologist with a child suffering from chronic suppuration of the middle ear, does he not hear that

the family physician pronounced it only a running ear and said that the child would outgrow it. Only too often the disease outgrows the patient and it can never be trusted to continue benign for any length of time. Dr. McCaw does not consider that radical measures should be employed in every case of running ear, but he pleads for appropriate treatment at the hands of some one who knows the precise significance and will be ready to recognize the danger signal. All cases of chronic discharge from the ear which show signs of tension in the antrum should be operated upon.

Irritable Bladder in Women. Dr. R. L. Dickinson, of Brooklyn, said that the irritability of the bladder in females may be divided into various types, due to nervous conditions, chemical or mechanical influences, hyperemia or other pathological conditions. The more is known of the irritable bladder of females the more rare are frequency of urination and other irritable symptoms considered to be reflex. In very few cases is it considered to be due to the old cause so frequently appealed to, viz., a tipping forward of the womb. The most common form of irritable bladder is due to nervousness and may be consequent upon school examination, upon an attack of hysteria, or upon general nervous irritability. It will not infrequently be found that any unusual excitement causes certain nervous women to have a sort of bladder crisis as the result of their nervous condition. A simple excess in quantity of urine passed, due to drinking too large quantities of water, or to the superfluous amount of hysterical urine, may cause such nervous irritability. Other mechanical factors are prolapse of the bladder itself, or prolapse of the urethra or dilatation of the urethra. A not infrequent cause is masturbation. Infectious elements may enter into the problem and a trigonitis due most frequently to gonorrhea may be the cause. On the other hand, affections of the genital organs are in some cases followed by vesical irritability. Many women complain at their monthly periods of a certain amount of vesical irritability. At times local conditions, such as an inflamed meatus, or a urethritis may be the cause. The most important consideration in beginning treatment is to look for the cause of the condition. The quantity and quality of urine must be judged and such conditions as the caruncle of the urethra or chronic inflammation of Skene's glands must at once be looked for. When these are inflamed, tiny red spots are visible when the urethra is slightly turned out. At times these glands take on the form of retention cysts. Sometimes there are on each side of the urethra little urethral flaps, minute nymphæ, as Kelly has called them. These are not physiological barriers to infection, as has been said, but are true examples of partial prolapse of the urethra. Not infrequently it will be found that the gaping of meatus will admit the finger tip. Sometimes the meatus appears perfectly normal, when the patient is in the prostrate position, but the pathology of the situation will be recognized at once if the examination is made while she is standing up.

Treatment.—In cases of prolapse of the bladder this should be fixed. The upper portion of the bladder is more tolerant of stitches than its base. If the uterus seems to be giving any trouble because of tendency to prolapse it should be suspended at the same time. Occasionally patients complain that every time that they cough or sneeze or even laugh violently, there is a gush of urine. The old plastic operation of twisting the urethra on its axis, which used to be performed in these cases, did not always give satisfactory results. In recent years, paraffin has been injected alongside the urethra, and this has given much better satisfaction, while the procedure has so far been associated with no inconveniences or sequelæ.

Uterine Fibroids.—Dr. W. E. Ford, of Utica, in giving his experience of uterine fibroids, said that twenty years ago he saw many more of them than at present, not because they were actually more frequent, but because they had not been operated upon and there was an accumulation of them, while now of course every town has its own surgeon who can operate upon them without any hesitation. Dr. Ford has tried many ways and for a number of years employed electricity. This seemed to improve the general condition of the patient and not infrequently to cause small fibroid tumors at least to decrease in size. In some cases, however, no effect at all seemed to be produced. In one case there was a death in the use of the electric needle. This was due to infection from a gonorrheal salpingitis, which set up a rapidly fatal sepsis. He employed ergot in a certain proportion of cases, and while he found some improvement in the symptoms, especially in a decrease of her hemorrhage, from its use, he does not think that this ever made the tumor any smaller. At times, when the tumor is of the submucous variety, the contractions in the uterine wall set up by ergot, forced the tumor into the lumen of the uterus, and thus made it easier to remove. With regard to the tying of uterine arteries for the purpose of reducing the size of fibroids, Dr. Ford has not had any special success. The catching of the arteries is a difficult indefinite method without any satisfaction and involving considerable risk. Dr. Ford used thyroid extract in a number of cases, but does not think that there was ever any special benefit from it and does not think that this substance has any control over hemorrhage. He used adrenalin, however, with excellent results as regards hemorrhage. Now that uterine fibroids are usually smaller when they come under observation than before, operation is the most suitable method of treatment. Dr. Ford has operated sixty-one times in 15 cases, having to cut the tumor into pieces in removing it.

Treatment of Diffuse Septic Peritonitis.—Dr. Russell S. Fowler, of Brooklyn, gave the results of 100 cases of diffuse septic peritonitis treated by thorough drainage of the abdominal cavity with the head and trunk in an elevated position. No case was refused treatment no matter how desperate it seemed, and though these cases are usually considered hopeless, sixty-seven of the patients recovered. Most of the cases of general peritonitis followed rupture of the appendix. The technic of the method of treatment included the making of a small incision, only sufficient to enable the operator to get at the diseased parts, the isolation of the chronically inflamed region with laparotomy pads, and the washing out of the septic parts with peroxide and a saturated solution of bicarbonate of soda. After the foaming was over the peritoneal cavity was washed out with normal salt solution. All pockets of pus were opened up and flooded with hot saline solution. The intestines were not allowed to escape during any portion of the treatment. Drainage was made as perfect as possible. Usually a glass tube was inserted in a piece of rubber dam and wicks of gauze were carried down to the bottom of it so as to draw up any material that might gather in the pelvis and yet allow of the aspiration of the tube occasionally. If many pockets of pus were found throughout the abdominal cavity, from twelve to twenty wicks of gauze were carried into these. The patient's head and trunk were elevated at least one foot, sometimes more. This was accomplished by raising the upper end of the mattress over a special arrangement in the hospital or over

the back of a chair. All of the cases improved immediately, at least for the time being. The vomiting stopped, if there had been any, and gas was freely passed by the rectum. Only in three very septic cases was there failure of this improvement noted.

Asthenopia.—Dr. D. H. Wiesner, of New York, said that the complaint of weak eyes and of poor sight was becoming more and more prominent. This is partly due to the increased use of the eyes under artificial light, but it is also due to a general deterioration of the nervous system in the rush of life and the fierceness of competition in our cities. Weak eyes are not found so commonly in the country. The frequency of weak eyes can be noted from the number of signs of refracting opticians to be found on the streets. Besides these, at least 50 per cent. of the oculist's work is concerned with eye-strain. Under many hours of artificial light the ciliary muscle gives out. The most important part of treatment of these conditions is an improvement in the general nervous tone of the patient and the insistence on a better living environment.

Eye Muscles and Others.—Dr. Lucien Howe, of Buffalo, N. Y., demonstrated how the normal muscles of the body may be tested and their strength expressed in symbols. He then called attention to the fact that the strength of the muscles of the eye correspond to those of the body. He has made a series of observations upon soldiers stationed near Buffalo and found a distinct ratio existing between the ordinary muscularity and that of the eye muscles. It is important, when there is some defect in the musculature of the eye, to treat the patient by a general development of muscle tissue, which will eventually bring with it an improvement in the eye muscles also. If this should be accomplished there would be no need for so many tenotomies as there are at present and there would not be so many serious reflexes set up because of failure of muscle balance.

Diagnosis of Glaucoma.—Dr. D. B. St. John Roosa, of New York City, said that while specialists complain of encroachment upon their special fields by the general practitioner, this is not true of the eye specialist, and while for such conditions as cataract or strabismus it is the ophthalmologist who should see the case, there are many conditions of the eye that the general practitioner is bound to recognize or else serious harm will result. Glaucoma is one of these and the most important. It has an unfortunate name, since the greenish swelling implied by the name glaucoma, a greenish-grey tumor, is only in the last stage of the disease, and it should be waited for, will prove the loss of the patient's sight. Unfortunately, if not diagnosticated, it will cause the loss not alone of one, but usually of both eyes. The most important symptom of the disease is the increase in the tension of the eyeball. General practitioners should accustom themselves to the recognition of normal tension in the eye by the habit of palpating normal eyeballs.

Course of Glaucoma.—Patients suffering from this severe affection are usually past middle life and give a history of arthritic tendencies; they come to the physician with a watering eyeball, or with a red zone around the cornea. They complain of dim vision and pain, which is of very distressing character and sometimes gives rise to the mistaken diagnosis of neuralgia of the eye. There is no such thing as a neuralgia of the eye, in the ordinary sense of a neuralgic pain not due to some serious condition. It will be found that their cornea are insensitive. The eyeball will be found distinctly hard to the touch. If such a case is neglected, blindness is inevitable. The treatment needed for these cases is the insertion of some eserine solution of the strength of two grains to the ounce. This at once gives the patient some relief. If there is any further progress of the symptoms an irredectomy must be done. Some of the ideas with regard to glaucoma are needlessly confused by the extraordinary nomenclature which has gathered around the affection; there is acute, simple and chronic glaucoma, then fulminant, hemorrhagic, prodromal, evolutum, absolutum, and primary and secondary glaucoma. But these are the only terms that should be used.

Climate of Long Island.—Dr. W. H. Ross, of Brentwood, Long Island, called attention to the fact that while Long Island is often considered to be the home of marshes, malaria and mosquitoes, the actual state of affairs on the Island is very different. It consists mainly of a dry, sandy plain. Its nearness to the ocean makes it much cooler in summer time than New York City, or the regions lying farther inland. On the other hand, the ocean has during the winter time a tempering influence on the cold, so that the average cold is not nearly so severe as in New York City. The mortality of the Island is very low, compared to other parts of New York State, or of New Jersey, and it compares very favorably in this respect with the Berkshire Hills in Massachusetts. When the true climatic conditions that exist on Long Island come to be recognized, it will be used by New York physicians much more than at present as a place to which patients will be recommended in many chronic conditions. It is especially favorable for chronic nervous affections and for insomnia. Visitors are often surprised at how well they sleep and for how long, though this had been one of the symptoms giving them most bother before they came on the Island.

Placenta Previa.—Dr. Scully, of Rome, N. Y., discussed nine cases of placenta previa that he has had under observation, for one of them, which occurred quite recently, he was called in consultant practice and understood that the woman was bleeding very severely. When he reached the apartment he found the floor covered with blood and all the clothing wet with it. He found, however, that both child and placenta had been delivered and that the woman was bleeding no more. The placenta was wrapped over the child's head somewhat like a hood and had evidently been forced out in this position under the influence of active contractions of the uterus in a strong woman. This gives an excellent idea of how nature is sometimes able unassisted to overcome the danger from placenta previa. It shows, too, the necessity for active interference in order to secure delivery of the child if the mother is to be saved, for the only hope of cessation of bleeding is in the firm contraction of the uterus. Dr. Scully believes in podalic version in order to facilitate rapid extraction in these cases.

Treatment of Cancer by Its Own Toxin.—Dr. P. J. McCourt, of New York, described certain cases of cancer treated by means of toxins obtained from cancers removed from other individuals. A glycerinated product is used for this purpose and the dosage is by the mouth. The difficulty is, according to Dr. McCourt, the selection of the proper form of toxin. As far as possible the toxic material used must have been obtained from a cancer in the same stage as that which is under treatment. During the use of the remedy not much animal food must be consumed and all stimulants, especially malt liquors, must be avoided. All strong liquors become absolute poison. The result of the administration of this material is the occurrence of a critical diuresis, diaphoresis, diarrhea and erythema. The remedy must be employed about twice a day, in the morning and evening, when the stomach is empty. In mammary cancer and in uterine cancer good results have been obtained. This remedy

has proved also of good service in the treatment of lupus. It may be employed with decided advantage after operation to prevent the recurrence of cancer.

Radioactivity.—Dr. J. S. Wight, of Brooklyn, discussed recent researches in radioactivity and electricity with their bearing on radiotherapy and the legal status of these new remedies. With regard to radium he insisted on the possible good effects that would be obtained in malignant disease and in other forms of external affections. He also suggested the possibilities of a transmitted radioactivity proving useful in the treatment of internal affections. With regard to the Roentgen rays, he showed the possibility of using certain secondary radiations that are contained in the Roentgen rays, which promises to do away with the danger of burns and yet retain all the therapeutic activity of this peculiar source of energy. He considers that as yet medicine is only entering upon the discovery of a series of the therapeutic results of great importance in the employment of these new materials and forms of radiation. With regard to the legal status of their use he insisted that only those who are experts should be allowed to give evidence in trials where such remedies have been employed and suggested the possibilities of blackmail that are involved in injuries that may result or in supposed failures to cure. Dr. Wight suggested that the heating of radium had a definite effect upon its radioactivity, and that it seemed not improbable that the employment of heat would be an important adjunct in treatment by means of radium. He also suggested that any negative electric body, if held in the air becomes radioactive, and though this radioactivity gradually disappears afterward there are evident possibilities of the use of this form of energy without an expensive outfit such as might be required for large quantities of radium. Even rain drops become radioactive during their passage through the atmosphere. When this radioactivity exists on metals it disappears when the superficial surface of the metal is dissolved by means of acid. This seems to be a proof that it exists only on the outside of the radioactive bodies. A curious phenomenon is that the acid becomes radioactive, though it does not retain this property for a long time.

Mineral Waters and Radium.—In certain mineral waters a radioactive gas has been found. In so many different forms of mineral waters has this been true that it has come to be a general opinion that the radioactivity of mineral waters is the important element in their therapeutic effect. It has long been known that artificial mineral waters, though made to conform as closely as possible with the chemical contents of natural mineral waters, never act quite as efficiently, nor do the salts abstracted from mineral waters and then redissolved in water prove as efficient. It would seem that in the phenomena of radioactivity, there may come the explanation of a very vexed problem in therapeutics—the effect of natural mineral waters.

Lesions Around the Knee-joint. Dr. Nathan Jacobson, of Syracuse, said that there are a number of lesions around the knee-joint which may easily lead to confusion in diagnosis. One of these and perhaps the most important is acute osteomyelitis, which usually follows some trauma, but may not necessarily do so, and is mistaken not infrequently for acute rheumatism. He has found abscesses forming bone and cause the separation of large sequestra because of the formation of pus in cases where the beginning symptoms of the disease gave no idea of the seriousness of the affection. Besides osteomyelitis tuberculosis is of course, frequently around the knee-joint. One of Dr. Jacobson's recent cases was a tuberculous abscess at the head of the tibia, though there was no involvement of the knee-joint itself. There are certain lesions that seem to occur by preference near the knee-joint without known cause. One of these is sarcoma. It must not be forgotten that if these tumors are recognized sufficiently early and are not of an especially malignant variety, amputation high up will prove life-saving. Round-cell sarcomata have not a very favorable prognosis, however, recurring in spite of amputation. Spindle-cell sarcomata usually do not recur. In a recent case under Dr. Jacobson's care tuberculous affection of the femur presented most of the supposed pathognomonic features of sarcoma, including even fracture of the bone for a very slight cause, yet proved on careful pathological examination to have no malignant elements at all.

Surgical Cases in Albany.—Dr. Albert Vander Veer, of Albany, reported 615 surgical cases attended at the Albany Hospital during the year 1902 and the beginning of 1903. He found that with regard to fractures of the jaw, after having gone through all the supposed improvements of wiring and new-fangled splints of many minds, that the best method of treating these cases is by the application of an interdental splint. For this purpose a dentist is attached to the hospital staff and there is no doubt that patients have a greater degree of comfort and that these fractures heal sooner with less anxiety on the part of surgeon and patient, and with better results than under any other circumstances. Dr. Vander Veer considers that enlarged glands in the cervical region should be removed early. They constitute a focus of disease that may easily spread. Patients should be impressed with this idea. Otherwise enlarged cervical glands are allowed to remain and become the source of generalized infection, or later in life, of pulmonary consumption. Treatment, except eradication, is almost sure to be disappointing, and consequently it is better to advise radical measures. With regard to cancers Dr. Vander Veer has had excellent results by doing the complete operation, removing the glands in the axilla, as well as above the clavicle. In all cases of tumors of any considerable size the pectoralis major and minor muscles were also removed. With regard to sinuses of the gall-bladder region, after operative procedures, he has not had the difficulty in securing closure that so many surgeons find, because by dropping from three to five drops of pure carbolic acid into the sinus he has succeeded in causing them to close. In one operation done subsequent to a laparotomy that had been followed by hernia, one of the most serious complaints made by the patient before operation was of pain in the scar. This took the form of acute discomfort, as if she were being pricked by a needle. During the hernia operation a hypodermic needle that had broken off near the shoulder was found imbedded in the scar. It was no wonder that she had a pricking sensation. Nothing was said to the patient after the operation, and she left the hospital no wiser than before. After hernia operations, Dr. Vander Veer does not believe in the use of a truss, as it serves rather to weaken the abdominal wall at the point at which it is applied than to protect the intestines from protrusion.

Gunshot Wound of the Brain.—Dr. John A. Wyeth, of New York, described a case in which the patient was wounded by a bullet entering in the region of the forehead and evidently passing through the frontal lobes of the brain. It was thought that he was dead at first, and then that he would surely die, but the opening in the skull became plugged by granulation tissue and he recovered almost completely. There were no motor or special sense symptoms, though for a time the patient talked incoherently and had to be watched. There was considerable weakness of the right side, but no other special symptom. In operat-

ing the orbital plate was pierced in order to obtain drainage, and then recovery was without incident. All of his motor symptoms disappeared, but there has been a slight loss of intelligence. Considering that the operation was not done for several months after the accident, this seems to be an excellent result.

Tuberculous Myositis.—Dr. William B. Brinsmade, of Brooklyn, reported a case of injury to the leg on the outer side, which was followed after some time by swelling from the ankle almost up to the knee. This swelling was symmetrical and was evidently due to some pathological condition of the subcutaneous tissues. The skin was perfectly movable over the swelling. At first a sarcoma was suspected to be present, but a portion of the tumor was removed, and after careful examination proved to be typical tuberculous tissue.

Staphylococcus Aureus Infection.—Dr. Arthur G. Root, of Albany, reported some cases of *Staphylococcus aureus* infection, which had been observed in the industrial schools at Rochester. This microorganism often occurs in the skin, and may usually be found in the mouth, the nose and the ear. In the first case reported the patient suffered from a boil from which he seemed to have recovered entirely when about ten days afterward his right knee became swollen and painful. The swelling was not marked, but the tenderness was excessive. The temperature rose to 104° F. The case was diagnosed as acute rheumatism, but did not improve under the administration of the salicylates. After a time the lower portion of the thigh was found to be involved and an abscess in this situation was opened. Pus was found beneath the periosteum of the femur. The knee itself continued to be troublesome, and as the temperature was intensely septic, amputation finally had to be performed. The second patient had a run-around on the nail, which lasted for a considerable period, and finally led to some lymphangitis. One day his temperature rose to over 107° F. The sore around the finger-nail was then opened very completely and hot bichloride applications were made. Notwithstanding this the patient continued to have a chill every day and a temperature of 105 to 107° F. In fourteen days there were fifteen chills and the average highest temperature was 106° F. Careful examination of the blood was made and no plasmodia of malaria were found. Quinine produced no effect upon the temperature and the secretions were sent for examination to the Bender Laboratory in Albany. There a coccus was found growing like the staphylococcus and producing no color. It was considered to be the *Staphylococcus albus*, which very seldom, however, has anything like the virulence that seemed to be present in this case. After cultures of the microorganisms had been grown in the laboratory for ten days a certain amount of color appeared in them. After a time the golden yellow color was manifest.

Trachoma Treatment Without Operation.—Dr. Frank J. Parker, of New York, said that an impression prevails that all cases of trachoma need to be operated upon. This is not true and on the contrary most of them do better under careful non-operative treatment. Cases of follicular trachoma with soft lesions need to be operated. If trachoma is operated upon in the first stage operation is apt to be followed by hardening of the conjunctiva and irritation of the cornea with the production of pannus. This opinion, which was held by the older ophthalmologists, is now being generally accepted again. Where trachoma is under treatment it is important that special hygienic directions should be given the patient for the protection of others. The greatest care should be exercised especially as regard the hands. These must be cleaned often and the patient must be warned of the danger of communicating his affection. All patients suffering from trachoma must sleep alone and their handkerchiefs, towels, etc., must be absolutely personal. The patient's general condition is important. An outdoor life and good nutritious food must be advised. For local treatment the newer silver preparations, and especially argyrol, seems to be the most efficient.

Aphasia and Agraphia.—Dr. Edward E. Fisher, of New York, discussed sensory and motor aphasia, and especially their relation to agraphia and the possibility of the existence of a special center for writing. Sensory aphasia, he insisted, is often accompanied by some loss of the sense of the use of things, that is, a certain amount of apraxia. It is possible that there may be a special writing center, situated in the second frontal convolution. It seems much more probable, however, that the cases in which there was a supposed lesion of a special writing center were really affections of the association fibers of the various centers for speech. Professor Starr believes in the existence of a special writing center, but as people may learn to write with their teeth, or with their toes, either one of which parts is controlled by centers distant from the supposed writing center, the opinion does not seem probable. Dr. Joseph Collins says that there has never been a case of pure motor agraphia, and that there has always been some associated lesion. Hence there is no special writing center. With this opinion Dr. Fisher is in full accord.

Symposium on Abdominal Pain.

Abdominal Pain in General.—Dr. John H. Musser, of Philadelphia, considered especially abdominal pain consequent upon abnormal conditions of the stomach, liver and pancreas. With regard to pain in the abdomen, he insisted that where toxemia existed, the physician should be very wary of coming to conclusions entirely dependent on the complaints of the patient. Under these circumstances not unfrequently the patient is not able properly to locate or to tell the character of his pain. Spasm of the abdominal muscles always accompanies pain in the abdomen when it is severe, but will not be found in women with very distended abdomens. Rigidity is much less marked in women than in men, owing to the fact that their muscles are weaker. Toxemic conditions induce apathy. When rigidity is absent, if leucocytosis be present, too much stress must not be laid upon this fact since the leucocytosis is evidence of the existence of a serious condition. In athletes intense muscle spasm may take place and even a slight colic may produce board-like tightness of the abdominal muscles that would seem to indicate some mortal illness.

General Abdominal Pain. In intoxications, as in uremia, for instance, or, as the French say, in affections of the kidney, especially those connected with pregnancy, pain is apt to be a forerunner of other uremic symptoms. It is usually situated in the epigastrium, or in the right or left hypochondrium. It is not unusual to find that such nephritic conditions have been diagnosed as due to gastritis. Chronic gastritis may, however, give a sense of discomfort, though it must not be forgotten that there are many referred pains in this region and that the pancreas and the gall-bladder, as well as the pylorus, may all cause manifestations in the epigastrium. It used to be the custom to talk of hysteria as causing pain in the abdomen. The rôle of hysteria has become narrower, however, as diagnosis has become better, and it is a good maxim that the word neurosis covers a deficiency of diagnosis, whether that deficiency be due to the physician or to the present state of medicine. The more so-called hysteria Dr. Musser sees the more he thinks that there is some lesion present. It must not be forgotten that aneurism

not infrequently causes abdominal pain. Caries of the vertebræ may also cause it. The spondylitis deformans described by Marie may be a source of abdominal pain apparently because of the crowding and uncomfortable position of the abdominal organs which it causes. Certain neurotic conditions connected with neuritis, as for instance diaphragmatic rheumatism, these may give pains simulating perihepatitis. In a case under Dr. Musser's care not long since, the patient was operated upon for hemorrhoids, and when the diaphragmatic pleurisy developed for a time there was serious fear that perhaps infecting material had found its way along the portal veins of the liver and set up a serious condition around this organ.

Transferred Pains.—Pneumonia not infrequently causes pain in the abdomen and no pain in the thorax. This is especially true in children. It may simulate appendicitis, or at least acute peritonitis, and operations have even been performed with a mistaken diagnosis where subsequent investigation showed the existence of pneumonia. Sometimes, however, pneumonia is central and does not develop enough to be recognized for several days after the operation. Pericarditis may occasionally cause epigastric pain. The pain of pleurisy may also be transferred and apparently be much lower than it really is, or it may be reflected along nerves leading to abdominal muscles. Angina pectoris not infrequently causes pain that resembles an affection of the stomach. On the other hand, the congestion of the liver due to a failing heart may give rise to a suspicion of the presence of gall-stones. The liver becomes quite tender and may be also acutely painful. The pain of pyloric spasm may simulate gastralgia and may also be mistaken for cholelithiasis. Occasionally when pain is to be expected it may be absent. Gangrene, of course, may proceed absolutely without any pain in certain recently described cases. Intussusception has occurred as the result of paresis of the intestines from thrombosis of the abdominal veins, and yet, notwithstanding all these severe pathological conditions, no pain was present. The reason for all this was easy to see when operation was performed, as there was absolutely no peristalsis at all. The intestines were as limp and motionless as an autopsy, and there was the eery feeling of a living autopsy. Slapping and hot applications had no effect in bringing on peristalsis, and the patient died.

Pain in the Abdominal Walls.—Dr. Joseph D. Bryant, of New York, said that pain in the abdominal walls was always referred along to the distribution of the spinal nerves. This often causes a very pretty demonstration of the distribution of nerves in such diseases as Pott's disease. This affection is not infrequently missed. In three cases recently under Dr. Bryant's care, the spinal deformity was not marked at all, and in at least one case would not have been discovered, except by an expert. Certain localizations of pain have a definite significance. In the iliac region pain with tenderness and rigidity means mostly appendicitis. It must not be forgotten, however, that pain may occur in the abdominal walls without there necessarily being any organic affection beneath. There may be an intercostal neuralgia of the abdomen, even though there are no ribs, the nerves corresponding to those in the intercostal spaces being distributed to the muscles of the abdominal wall, as regularly as in the thoracic region. It would be possible for the reptilia, without any ribs, to have a series of intercostal neuralgic pains all along their bodies.

Pseudo-Appendicitis.—With regard to appendicitis it must not be forgotten that certain functional neurotic conditions may be of importance. A patient recently admitted to Bellevue, after an alcoholic debauch, claimed that he was suffering from all the subjective symptoms of appendicitis. There was even some slight fever and, of course, some rise in the pulse rate from the effects of the alcohol. He asked that his appendix be removed. There was already a scar in the appendicial region, and careful inquiry elicited the fact that his appendix had been removed at another hospital, when he was complaining of the same set of symptoms, though nothing wrong was found with it. A second operation had even been performed at a third hospital and now the patient was once more ready to be operated upon. In certain cases highly neurotic females are apt to be so taken by the idea of appendicitis as to simulate for themselves its symptoms. In one case operated upon it was found that the girl had never had an appendix. That organ was represented by a slight puckering of the cecum and nothing more. Some time afterward she developed the same set of symptoms for which she had originally been operated on, and the surgeon at another hospital was about to make an incision in the line of the old scar when he thought it better to consult the records of the previous hospital, when he found what was the true condition. The pleural nerves are distributed or at least are joined by branches to certain nerve fibers that are distributed over the upper part of the abdomen. This important fact must not be forgotten. Surgeons will find that they are greatly helped in making the diagnosis of conditions accompanied by abdominal pain and tenderness if they look up carefully the nerve supply of the part of the abdominal walls affected.

Intestinal Pain.—Dr. Frederick Holme Wiggin, of New York City, discussed the diagnosis of conditions which cause intestinal pain. He gave the details of the parts of the intestines and the special forms of pain caused by affections in them. Tenesmus characterizes an affection of the rectum or lower part of the colon, repeated colic is indicative of enterostenosis; appendiceal pain is localized in the right iliac fossa, duodenitis gives mucus in the stools with pain in the right hypochondrium. In children under four years of age sensitiveness along the course of the colon, accompanied by intense griping pains, is caused by enterocolitis. Definitely localized pain accompanied by increase of peristalsis, with the formation of a tumor due to distended coils of intestine, is indicative of occlusion of the intestine. Lead colic would seem to be easy enough to recognize, especially when the occupation is taken into account and the blue line can be found on the gums, yet it is the experince of almost every surgeon to find occasionally that patients are supposed to be suffering from some other intestinal condition when it is really lead colic. Tuberculous peritonitis would seem to be reasonably easy of recognition, especially when it is remembered that before the occurrence of ascites enlarged glands may sometimes be felt in the abdomen and the condition is always accompanied by a gradually growing discomfort. It sometimes happens nevertheless that this condition develops so insidiously that when young patients are brought to the surgeon the ascites is the principal symptom. Most of the suddenly developing painful conditions referred to in the intestines require immediate operative interference. On the other band, not all sudden pains are appendicitis. Typhoid fever has been mistaken on a number of occasions for appendicitis, and the differential diagnostic signs must be borne in mind. In typhoid fever the temperature runs high, the pulse is usually low as compared to the amount of temperature, and there is a low leucocyte count. In appendicitis the fever is usually not marked, the pulse is high, and the leucocyte count is one of the characteristic signs of the condition, the white cells being

very frequently increased to twice or three times their ordinary number.

Pneumonia and Appendicitis.—There might seem to be no possible connection between pneumonia and appendicitis, and no possibility of mistaking one for the other. As a matter of fact, however, pneumonia not infrequently causes an acute pain in the abdominal region. Pneumonia of the right lower lobe may by reflex action cause pain in the lower right quadrant of the abdomen that may easily be mistaken for appendicitis, as the pulse and temperature are sure to remain high; operations have even been performed, but as pneumonia patients are not good subjects for operations, the result is usually fatal. The best differential sign is the pulse respiration ratio. If the respirations are increased more than they should be considering the height of the pulse then there must always be suspicion of pneumonia involvement.

Undigested Symptoms.—Dr. Robert F. Weir, of New York, said that a distinguished financier remarked, not long ago, that the stock market was all right, but that there were a number of undigested securities. A similar remark might be made with regard to the pain symptoms of abdominal conditions. Our knowledge of diagnosis is all right, but there are a number of undigested symptoms whose exact value must yet be determined. It is extremely difficult for the surgeon to decide not only what to do, but when to do it, and most important of all for him to decide when not to wait. As a rule the surgeon must either make his diagnosis and then the decision as to operation from that, or else he must make an exploratory laparotomy. There is no doubt that often he does not know exactly what the condition is, yet he must conclude as to the advisability of operation. Formerly the surgeon was much more interested in the lower half of the abdomen. Now it is the upper half that is attracting attention. There are a number of important organs, any one of which may become affected in such a way as to require surgical intervention. Besides the gall-bladder and its manifold ills there is always the question of perforation of the stomach or of the duodenum, or of the various forms of pancreatic disease. Besides McBurney's point, with regard to which something will have to be said later, there is Mayo Robson's point, one inch above and to the right of the umbilicus, at which tenderness and pain means an affection of the gall-bladder, usually the presence of calculi in that viscus and subsequent infection. Besides the gall-bladder, however, in recent years the pancreas has come to attract much attention, and not infrequently it happens that for acute infections of the pancreas, the surgeon only finds them when he has operated for something else. With regard to the upper abdomen, it must be remembered that the pains of appendicitis may be reflected upward or those of pleurisy downward, simulating an affection in the upper portion of the abdomen that does not really exist. Dr. Weir considers that the sign suggested by Dr. Eliot, of New York, may prove helpful to surgeons in the recognition of affections of the pancreas. Ordinarily, if the hands are placed upon the patient's lower ribs, the thumbs inward along the costal arches and pressure is made, the ribs will yield one-half an inch to an inch. If there is trouble in the liver or in the pancreas this will not occur, but there will be resistance to the inward pressure and considerable complaint from the patient. Dr. Weir has found this to be true in a number of cases. On the other hand, Dr. Eliot has destroyed the illusions which exist that there is no leucocytosis in pancreatic disease. This makes it more difficult for the surgeon to recognize the condition. Dr. Weir has not found Head's discoveries of much value in practical diagnosis. The areas mapped out by him are undoubtedly connected with the organs he suggests, but in practice this set of symptoms does not furnish sufficient basis for the justification of operation. He does not consider that the ordinary location of Burney's point is as absolute as it is sometimes thought to be. Instead of the point midway between the anterior superior spine and the umbilicus, he has found in a number of cases that the point of tenderness is midway between the umbilicus and the end of the outer third of Poupart's ligament. This will bring it considerably below the ordinary location of McBurney's point. He has discussed this subject with Dr. McBurney himself, who considers that too absolute location must not be insisted on. With regard to palpation of the appendix Dr. Weir does not consider with Dr. Edebohls that this organ can be palpated through the abdominal wall, but in thin subjects, in cases of chronic thickening of the appendix, if, while the surgeon's fingers are pressed into the right iliac region over the appendix, while the patient is asked to lift up the right leg, the organ may be felt. The reason, of course, is not far to seek, as the psoas muscle in its contraction presses the appendix up against the downward pressure of the finger. In children Dr. Weir considers that it is advisable to sweep with the finger in the rectum over the right iliac region in order to recognize the condition that exists there.

Third Day—January 28th.

Recurring Membranous Stomatitis.—Dr. Lewis E. Blair, of Albany, reported a case in which there was a membranous affection beginning in the throat and gradually spreading over the mouth, coming on in subsequent attacks and on one occasion affecting all the visible mucous membranes. At first there was the appearance of simple ulceration followed by the formation of membrane within the mouth and then, as this got better, by the appearance of various lesions on the skin. This patient had a series of these attacks, the first relapse being very severe and occurring a year later, a third attack somewhat mild in character some months afterward, and a fourth attack, the severest of all, lasting six weeks. In this attack nearly all the mucous surface of the fauces, the pharynx and the mouth were covered. Even the palate, except the uvula, the tongue was so swollen as to make articulation very difficult. There were mucomembranous patches on the anus and in the urethra. The subsequent skin lesions began as erythema, then became vesicular in character, the fluid contents, however, were somewhat bloody and giving the appearance of hemorrhagic smallpox.

Skin Eruption.—This took the form of Hebra's erythema exudativum multiforme and ran through its stages, different groups occurring successively; while certain of the erythematous patches were in process of cure this gave the appearance of erythema iris. Oleate of mercury was employed as a salve on the body in one or two places, and wherever it was used the eruptions were especially severe. During the course of his severest attack, a troublesome bronchitis developed. This was considered to be a manifestation on the mucous membranes of the same conditions noted on the skin. Just when this was thought to be getting better a wandering pneumonia set in which lasted for a considerable period. Extensive desquamation took place, and as most of the skin had been involved this also lasted a long time. The secretions were examined bacteriologically three times by Dr. Blumer, who found in them only cocci, mainly staphylococci.

Optometry Bill.—Dr. Lucien Howe, of Buffalo, introduced a resolution instructing the legislative committee to oppose the passage of the so-called optometry

bill, which permitted the licensing of physicians. This practically put the delicate business of treating eyes suffering from refractive errors in the hands of uneducated men, who knew nothing, except the mere empiric details of fitting glasses. There was already sufficient abuse in this matter without its being licensed by law and the passage of the bill should be prevented. It was hoped, too, that this action of the New York State Medical Society would make physicians realize that they must not encourage its passage in any way.

Hospital Car.—Dr. W. W. Sanford, of New York, said that the necessity for having a car specially arranged for the reception and treatment of persons injured on railroads was now very clear. During the last few weeks three sad accidents followed by appalling loss of life and severe injuries had emphasized this necessity. Experiments had been made in this direction and it was found that an ordinary baggage car so arranged that the baggage compartment served as the operating room or rather the reception ward, while the rest of the combination car served for cots, made an emergency hospital car of a satisfactory kind. It was important, however, that railroads should not trust their injured to chance, and that there should be deliberate arrangements made for immediate aid to the injured after accidents.

Special Hospital Car.—One of the railroads has recently given an order for the construction of a special hospital car sixty feet long, divided into two compartments respectively, forty and twenty feet each. The twenty-foot compartment is meant to serve as an operating room, and is to be finished with attention to every modern surgical aseptic detail. The inside of the car is to be of hard wood that will stand thorough washing, and the floor is to be constructed of rubber tiling flexible enough to yield somewhat to the motion of the car, and yet be hard enough to secure a thoroughly clean floor. All the arrangements within the car are to be of glass and metal so as to stand cleansing, and it is to be separated from the other compartment by glass doors. A special conductor with physician and nurses are to be ready to occupy this whenever needed, and it is to be kept standing on a special track, so that it can be hurried immediately to the scene of an accident. When it is recalled that during the recent accidents men and women died in barns and cabins, and sometimes by the roadside, with no other help often for hours, except a physician who had himself barely escaped with his life, it is easy to understand how much this hospital car will bring of alleviation for suffering. Every railroad in the country should have one.

Symposium on Nephritis.

Pathology of Renal Decapsulation.—Dr. William Murray, of Brooklyn, read for Dr. J. M. Van Cott, of Brooklyn, a paper on renal decapsulation from the pathologist's point of view. Dr. Van Cott described the renal circulation and insisted on the points with regard to it that seemed to make it impossible for renal decapsulation to make any change in the circulation. Virchow and Cohnheim showed that whenever the renal arteries were thrombosed, whether from oligemia or any other cause, the consequence always was a series of depressed cicatrices. The cortex of the kidney did not regenerate, and the capsule became adherent over the depressed areas and thickened while strands of connective tissue from it dipped into the substance of the kidney. When the kidney circulation is interfered with, either by the tying of the artery or the vein, swelling of the kidney takes place. This is due to the fact that the circulation from the capsule brings blood into the kidney, but not in sufficient force to carry it through the kidney substance. Whenever the capsule is removed and the blood vessels ligated, this swelling does not take place. The very fact of the removal of the capsule then would seem to hamper the aid that might be furnished a deceased kidney from this source.

Restoration of Kidney Substance.—It has always been a question whether the kidney substance would regenerate, and by far the great majority of opinions have been against any such regeneration. It is certainly not to be expected that the removal of the fibrous capsule and the adhesion of the fatty capsule of the kidney would bring relief. All the circulation in the fatty capsule is away from the kidney. Besides, when the capsule becomes adherent there is always serious injury to the cortex, produced because adhesions are formed by means of connective tissue, and during the course of contraction, this always interferes with the nutrition of parenchymatous structures near it, and consequently injures them seriously. As a matter of fact, one would expect a sclerotic condition to be set up in the cortex of a decapsulated kidney.

Causes of Chronic Nephritis.—The ordinarily accepted causes of chronic nephritis are not of a nature that would make one expect relief from decapsulation of the kidney, even though, as is claimed on theoretic ground, there should be an increase of the circulation secured by this means. Chronic nephritis is not an affection of the kidney alone, or at least is not considered to be primary to the kidney. It is always a manifestation of symptoms of general disturbance of the organism. It is due either to the presence of toxins in the blood which the kidney tries to eliminate and proves inadequate to the task, or to a connective tissue hyperplasia, beginning in the blood vessels and spreading to the tissues between the cells of the kidney. In neither of these cases could relief be expected from increased blood supply, even if this should be obtained. If there is an increased blood supply that brings with it more toxins than before, while the previons amount of toxins were causing destruction of renal tissue, the last state will be worse than the first. If there is already a tendency for sclerosis of blood vessels not much relief would be afforded by other blood vessels sharing this same tendency, because the arteries all over the body are thus affected.

Experimental Evidence.—Dr. Van Cott and Dr. Murray removed the capsules from the kidneys of cats in order to ascertain the result. Cats were chosen because these animals are especially resistant to infection. In some cases the capsules were simply stripped from the kidneys and then the organ put back. In others the kidney was made fast between the layers of muscle at the back, in order, if possible, to secure better adhesions, and consequently a better blood supply. In all of these the capsule was regenerated and the new fibrous tissue envelope was thicker than before, and sent down projecting strands into the kidney substance. In one case a cat was found apparently suffering from kidney disease, at least the animal was in bad general condition, and there were albumin and casts in the urine and at operation a large white kidney was found. This animal, however, was not improved by the operation.

Surgical Treatment of Nephritis.—Dr. Willis G. Macdonald, of Albany, said that certain forms of nephritis, as for instance those due to calculi, and to a movable kidney, can certainly be benefited by proper operations. All surgeons who have operated on movable kidneys know that such operations are followed by the disappearance of casts and albumin. It seems probable, however, that the symptomatic nephritis, accompanied by low specific gravity of the urine, and non-toxic urine would not be affected by operation. The true toxic

nephritis, also, such as are due to alcohol, ether, etc., are not encouraging subjects for operation.

Renal Tension.—In certain of the infectious diseases irritation of the kidney substance sometimes causes an intense hyperemic congestion of the kidney. Surrounded as it is by the unyielding fibrous capsule, the secreting substance of the kidney is subjected to pressure which may prevent its proper action. Under these circumstances anuria is likely to set in, or at least a very great diminution of the quantity of urine, with symptoms of uremia. Reginald Harrison, the English surgeon, has spoken of this condition as glaucoma of the kidney. He suggests the splitting of the fibrous capsule in order to relieve the tension, and in a number of reported cases, has brought decided relief in patients who seemed to be doomed. There is no doubt that this form of operation upon acute kidney disease is effective. Surgery has demonstrated the possible benefits it may confer upon nephritis, and there is hope that the surgical horizon may prove to be even wider than has been taught.

Medical Treatment of Nephritis.—Dr. Beverly Robinson, of New York, said that the main principle of the treatment of chronic nephritis, or of the acute exacerbations of chronic nephritis, which constitute the principal source of kidney disease that comes for treatment, is to supplement the action of the kidneys by means of the skin and bowels. For this purpose patients must be advised to sleep between woolen blankets and to wear a long woolen nightshirt. It is always ill-advised for them to wear linen next to the skin. Where they are passing but small quantities of urine, a milk diet is very advisable, though the insistence on this must not pass the limit of common sense and experience. Large quantities of water are advisable, and if this is from some slightly alkaline spring, so much the better. In order to keep the skin active Dr. Robinson has found the wet pack better than almost any other form of treatment. Where there is any complaint of a feeling of discomfort in the kidney region particularly, and in most other cases of acute exacerbations of kidney disease, the application of dry cups over the loins is important. Next to this is the use of high rectal irrigation, with Kemp's tubes, which promotes diuresis, as well as tempting evacuation of the bowels. When symptoms are severe and the patient is not very strong, Dr. Robinson does not believe in the use of pilocarpine, as it may set up an acute bronchitis and produce excessive secretion, with consequent serious edema of the lungs.

Drug Treatment.—Dr. Robinson has found nitroglycerin of great benefit in many cases, and has been especially encouraged by the effects of the old-fashioned sweet spirits of niter, which give good results without any complications. With regard to the severer forms, in which uremic coma is threatening or convulsions are occurring, bleeding followed by infusion of salt solution is the indication, and where the convulsive symptoms are severe, inhalations of chloroform should be used. Though many consider that morphine should be employed in nephritic seizures, Dr. Robinson does not consider it advisable unless the seizures are very frequent, or in certain cases of puerperal nephritis. The inhalation of oxygen often seems to do good. Nausea consequent upon nephritis, will often be relieved by doses of Kirschwasser, which is a dry alcohol containing some prussic acid from peach kernels. For diarrhea prolonged irrigation of the bowels with hot saline solution seems to be the best. For the general treatment of the disease, potassium iodide, as employed by Ringer, often seems to be effective. With regard to morphine, if the pupil is contracted it should never be used. If it is dilated or normal morphine may be employed.

Edebohls' Operation.—In discussing the papers, Dr. De Lancey Rochester, of Buffalo, said that many cases of nephritis can be treated so successfully by means of medical measures that it is a mistake to subject such a patient in his weakened condition to ether and the knife. The medical man will never fail to relieve the nephritic symptoms by proper medical treatment, and especially local treatment in the loins. Dr. Rochester believes firmly in the use of hot sweats by means of heated air at home, even in the poorest house. All that is needed is the elbow of a stove pipe and an alcohol lamp. Pylocarpine hypodermically has in minute doses always done good work in Dr. Rochester's hands. It should be followed immediately by a hot air bath. Dr. Rochester has seen nephritis following diphtheria become entirely well after six years of care, and has another case under observation where, though the nephritis is seventeen years old, the patient has not much discomfort when directions are followed.

Popular Idea of Bright's Disease.—Dr. Samuel V. Ward, of Albany, said that he is afraid of pylocarpine, but believes in absolute rest and external warmth in the treatment of nephritis. The popular idea of Bright's disease is that it is an absolutely fatal disease within a year or two. Every physician has cases under observation, in which casts and albumin have been in the urine for ten, fifteen or twenty years. These patients are well for all practical purposes, except as regards their power of endurance. For the general treatment of nephritis, Dr. Ward has found arsenic and iron better than all other drugs put together.

SOCIETY OF THE ALUMNI OF CITY HOSPITAL.

One Hundred and Tenth Regular Meeting, December 9, 1903.

The Vice-President, Alexander Lyle, M.D., in the Chair.

Case of Carcinoma Recurring in the Pleura Two Years After Breast Amputation.—Dr. B. H. Wells reported this case. The patient was an unmarried woman, forty-five years old, who, in November, 1901, noticed a small, hard nodule in the lower outer quadrant of the right breast. It was not more than a half inch in diameter. The skin, on being moved over the tumor, showed slight dimpling. It was not adherent to the fascia—was freely movable. The axillary glands were not involved, and the general condition was good. A radical operation was done, the greater part of the pectoral muscles being removed, together with entire axillary contents. Recovery was uneventful. Dr. Jeffries, pathologist to the Polyclinic Hospital, reported that at no place around the periphery of the mass was any carcinomatous tissue to be found. The glands and lymphatic trunks were likewise free from involvement. The tumor proved to be an ordinary carcinoma. Running straight down from it was a slender whitish thread, so fine that it could hardly be seen with the naked eye. It led apparently directly to the pectoral fascia. Under the microscope, this thread proved to be a line of carcinoma cells that coursed down through this fascia. Evidently there was one small lymphatic vessel infected. Instead of going to the axillary glands, it passed apparently between the ribs. The patient remained in good health from Nov. 10, 1901, to October 8, 1903. On that date she suddenly developed signs of pleurisy over the lower portion of the right lung. There was no external sign of a recurrence of the carcinoma. In two days the right pleural sac was filled with fluid. A prom-

inent clinician did not think at this time that there was recurrence of the cancer. Paracentisis gave temporary relief, 37 ounces of a straw-colored fluid which coagulated into a thin jelly after being removed. It showed a moderate number of round white cells varying from one-third to five times the diameter of a red blood cell. In some no nucleus was visible. Some had a single nucleus, in others it was multiple. On October 13 the fluid removed was dark red. The patient was evidently failing rapidly, and on November 13 she died of recurrence. This case is of vital interest, because of the relationship of the pathological report to the prognosis. It is also very unusual to find the axillary glands absolutely free from involvement. The lymphatic drainage was evidently of artypical type.

Dr. A. Lyle said that he had so frequently seen recurrence in the manner described, that in removing the breast, he now always dissects from the axilla downward, instead of beginning from the lower portion and dissecting upward. The theory supporting this procedure is that it may be possible to squeeze some of the carcinoma cells through the lymphatics if the dissection begun from below.

Dr. P. A. Potter continued the report of a case which he had related in part at a previous meeting. The patient was a woman twenty-three years old, who had had a miscarriage the second or third month, and was again pregnant in the sixth month. A threatened abortion was stopped by the usual methods. Two days later the temperature rose to 105° F., no other symptoms being present. The temperature lasted for ten days. Five days after her temperature had been normal, it again rose, this time accompanied with much pain in the bones. On the strength of this, the diagnosis of grip was made. Again she recovered after five days without any focal symptoms. Later she had another attack of a similar nature. A physician and a surgeon from New York, both of high repute, were unable to make a diagnosis. It was finally remembered that she had a slight cystitis after an attack of typhoid five years ago. So the bladder was catheterized. The pathologist reported that it was undoubtedly a case of pus in the pelvis of the kidney. There were no renal or bladder symptoms. Under large quantities of water and full doses of urotropin, the temperature went down and the patient has been well since.

Dr. B. H. Wells said that it was remarkable that the patient did not present some local bladder symptoms. Save for this he had recently had a similar case which recovered under urotropin.

Hyperthyroidization Following Curettage.—Dr. B. H. Wells reported this case. A full report of this case will appear in a subsequent issue of The Medical News. The case was that of a woman, fifty-three years old, who had for six months suffered from metrorrhagia. Hemorrhage at this age is suggestive of carcinoma and immediate steps were taken to obtain a specimen for microscopic examination. The patient was nervous, thin and poorly nourished. Her thyroid was enlarged and she had suffered at times from extreme attacks of tachycardia. Before operation the pulse was 110: There was no exophthalmos. Dr. Bennett gave gas and ether. The pathological report was that the scrapings were not malignant. For two days the temperature was normal, progress being uneventful. Suddenly, about the fiftieth hour, she developed a pulse of 190 and a temperature of 105.5° F. The tongue became dry, and a violent diarrhea with brown movements subvened Her stomach became so irritable that food could scarcely be retained. On the fifth day of the attack, the blood showed no reaction for typhoid. The thyroid had meanwhile become very markedly enlarged. It transmitted to the hand a distinct thrill and expansile pulsation. From this time on she very slowly improved. The pulse and temperature having reached normal. No symptoms were referable to the uterus. The curettage was done aseptically and the fever was not in any way connected with the operation.

Dr. J. W. D. Maury said that the conditions described by Dr. Wells resembled closely the train of symptoms which frequently follow operations for the removal of the sympathetic ganglia or resection of the thyroid in Graves' disease, except that very few cases of recovery are recorded. The symptoms in this case differ also from those ordinarily described in the tardiness of their development. Cases reported by Kocher, Curtis and others show an average latent period of from twelve to thirty-four hours.

Dr. Charles G. Child, Jr., had a similar case last summer which terminated fatally. A multipara, forty years of age, was admitted to his service at the Polyclinic Hospital in July. She was sent in because of constant flooding. This had been almost continuous for the past six months. Although much run down, her resisting powers seemed sufficient to justify operation. She was found upon examination to have a large uterus, which had apparently undergone general fibrosis. It was hard, about six times its normal size, and the os was patulous. She had a mild degree of exophthalmos. Her pulse on admission was 110, and there was a slight enlargement of the thyroid. Vaginal hysterectomy was performed, the operation lasting a half hour. It was absolutely uncomplicated. No vomiting accompanied return to consciousness, and her condition was normal until the fourth day, when the thermometer in the ward reached a hundred—a prostrating heat wave having come on. Immediately her pulse shot up to 130, and her temperature to 104° F. Her husband said that she was always affected in this way during the extreme heat of summer, and the effort was made to ascribe her condition to this factor. On the evening of the fourth day, however, she became unconscious and remained in a semiconscious state for five days. Her highest temperature was 104.3 and her maximum pulse 184. She was with difficulty roused to take nourishment. On the tenth day after operation she died in coma. Smears from the intestines, the kidneys and the spleen showed no infection of the abdominal cavity whatsoever.

Dr. J. F. Terriberry said that the uterine hemorrhage was doubtless due to excessive vasomotor paresis from toxemia of thyroid origin, aided by the abnormal state of the endometrium. Bowel fluxes and other evidences of excessive gland secretion are frequent in Graves' disease, but hemorrhagic sweatings are rare. It would be interesting to know whether these patients perspire at the time of the bloody flux.

Dr. J. W. D. Maury said that there is no way of determining whether symptoms of acute thyroidism are to develop in a given case of mild exophthalmic goiter which presents itself for operation. They occur in only a small per cent. of such patients. If the sympathetic ganglia or the thyroid are operated on, the symptoms generally develop in twenty-four hours. In the present state of perplexity of the subject, both Dr. Wells and Dr. Child were entirely justified in operating, because there is no way of foretelling this fatal postoperative sequel.

Some External Diseases of the Eye Due to Rheumatism.—Dr. Richard Kalish said that the purpose of this paper was to call attention to those forms of diseases of the eye distinctly rheumatic in their origin, to which this causative factor had not yet been ascribed. Many patients with blear-eyes, distorted lids, and lost eyelashes, spotted corneæ and lessened sight

would have recovered with uninjured or but slightly damaged eyes had the direct cause been known. He took a very emphatic position in disbelieving the fantastic theory that rheumatic diseases are due to micro-organisms. The external diseases of the eye due to rheumatism are marginal blepharitis of the young adult, recurrent hordeoli, or styes, recurrent chalaza, circumscribed bulbar conjunctivitis, limited circumscribed bulbar conjunctivitis and striated keratitis. Marginal blepharitis is usually associated with the so-called strumous diathesis. This is the form which is most familiar to us, and which occurs in children up to the age of puberty. The rheumatic variety differs from this in that it occurs in early adult life; in that it is always bilateral, and in that there is no involvement of adjacent structures. Furthermore sight is rarely interfered with to any extent. The author closed by expressing the belief that if the suggestions made in his paper were more generally recognized by the profession, there would be fewer cases of chronically injured eyes. (This paper will appear in full in a subsequent issue of THE MEDICAL NEWS).

Dr. D. H. Wiesner, in opening the discussion, said that the Society certainly was greatly indebted to Dr. Kalish for a most useful and interesting paper. Blepharitis, conjunctivitis, hordeolum, chalazion and the other rarer conditions described are, it is true, all discoursed upon by the books, but it is unquestioned that no author has as yet assigned their cause as exclusively as has Dr. Kalish, to rheumatism. The usual teaching has been that marginal blepharitis is generally due to bad hygienic surroundings. This would seem to have been proved by the fact that improvement often is very rapid in cases of young children, who are often cured by being placed in better hygienic surroundings. In early adult life, however, eliminating bad hygiene and correcting refractive or muscular errors, do not by any means always effect the cure which may be promptly looked forward to in young children. Call it rheumatism or faulty metabolism, it is strange that this third factor has for so many years passed unnoticed. Chalaza, as is well known, is prone to recur. So marked is this tendency that patients become habituated to operations. If, by treating this rebellious condition by the salicylates a cure can be obtained, even if it be only in a small proportion of cases, a very great gain in the therapy of the eye has been achieved.

Dr. G. H. McAuliffe said that it seems strange to a man whose whole time is given to the treatment of the eye to hear general practitioners say naïvely that "they never touch the eye, except for conjunctivitis or inflammation of the lids." Many of these gentlemen cannot differentiate iritis from conjunctivitis. Dr. Kalish's paper has shown the general practitioner that eye diseases are by no means altogether local; that they are not always cured by local medicaments, and that there are many pararheumatic conditions which succumb to antirheumatic treatment. What their nature may be is a matter of speculation. But it has long been recognized that the salicylate of soda has an admirable stimulant effect on the ocular circulation. He believes that many cases of blepharitis are due to direct infection of the germ of sycosis. The general practitioner should beware of the use of local remedies.

In closing Dr. Kalish said that there had been so general an acceptance of the views expressed in his paper that little remained for him to say, except to emphasize the statement that rheumatism is not always the underlying cause of the maladies mentioned, but only of the neglected and so-called incurable cases. Many causes unquestionably operate to establish the pathological conditions, but when local treatments of all kinds have failed, and the diseased conditions persist, rheumatism is the cause. Defective metabolism exists and when this condition of lack of balance between waste and repair has been remedied, the formation of toxins arrested and their elimination accomplished, recovery is assured.

Treatment of Epididymitis.—Dr. Sherman K. Foote read this paper. He outlined the method of treatment employed in the Roosevelt Hospital Dispensary. Upon the development of pain in the epididymis all injections are stopped, the patient is sent to bed and put upon a fluid diet. Free catharsis is ordered, together with rest in bed, and mild urinary sedatives. Locally, in the most recent series of cases experimented upon, a new drug, which is an ester of salicylic acid, has been used. It is a clear liquid, freely miscible, with animal and vegetable oils. Medicinally, it is characterized by the fact that when painted on the unbroken skin, it is absorbed and circulates in the blood as sodium salicylate. This drug, when applied to the scrotum once a day, produces a local feeling of warmth, no inflammation of any import, but occasionally a fine desquamation. Within a period varying from twelve hours to seven days, the pain is very largely controlled. As soon as this has been accomplished, the swelling of the organ is reduced by the application of mercurial ointment locally and iodide of potassium internally, and by thorough strapping. In applying the straps, care should be taken to first confine the testicle to the lower part of the scrotum by a band of adhesive plaster passed tightly around the scrotum above the testicle. The strips which cover the lower part of the scrotum should begin and end at this circular band as a fixed point, and they should be drawn tightly at intervals of a few days each until the swelling has disappeared.

Dr. W. C. Klotz said he was glad to confirm Dr. Foote's observations. He believed, however, that in order to get the good results quoted by the author, it was essential that the application be made in the very earliest stages of the disease.

Dr. J. H. Waterman said that in the Hospital for the Ruptured and Crippled, where a great many of these cases congregate, it is customary to treat them with equal parts of the tinctures of belladonna and iodine.

ABDOMINAL PAIN OF INTESTINAL ORIGIN.*

BY FREDERICK HOLME WIGGIN, M.D.,
OF NEW YORK;
VISITING SURGEON CITY HOSPITAL, ETC.

THE importance of a correct interpretation of the meaning of abdominal pain, when considered in connection with abnormal intestinal conditions, can hardly be overestimated, as in all serious disorders of this portion of the body, the advent of pain in varying character and degree is often the first warning given that the patient is suffering from a disease, which if not promptly recognized, and the condition immediatly relieved by the performance of a more or less serious surgical operation, may soon terminate his life.

Failure to heed this warning or to reach a correct conclusion as to its cause has been in the past, and too often still is responsible for the untimely ending of many valuable lives; while delay caused by an effort to make an exact differential diagnosis in doubtful cases is still responsible for the high rate of mortality attending surgical operations undertaken for the relief of acute intestinal disorders. As Maurice Richardson, in a recent valuable paper, has forcibly said in regard to this subject:

"Can we by study, observation and reasoning, learn to interpret the cry for help, which through pain, the fatal lèsion utters? Can we understand the cry which says, help the perforated stomach, the gangrenous appendix, the bleeding artery, the ruptured gall-bladder and the obstructed intestines?"

Abdominal pain, as has been stated, is common to all serious disorders of the intestines; its peculiarities in only one or two instances however, being sufficient, when considered alone to at once suggest to the physician's mind the general character of the disease; consequently in arriving at a reasonably correct diagnosis, in the cases we are discussing it is necessary to take into consideration, in addition to the pain, other important factors, such as the previous history of the patient and other accompanying bodily symptoms.

In a general way it may be stated that abdominal pain of a sharp and persistent character indicates involvement of the peritoneum whereas, a dull and aching pain points to involvement of the connective tissue only; while a cardialgia considered in connection with abnormal intestinal conditions, would limit the disease to the duodenum; tenesmus indicates limitation of the disease to the lower third of the intestinal tract; whereas, colicky pains occurring several times a year in the same person, who is not habitually constipated, would, according to Hemmeter, be suggestive of entero-stenosis.

Duodenitis.—A constant abdominal pain, with increased sensitiveness to pressure in the right hypochondriac region, occurring in a patient suffering from an acute gastritic, and in whose stools there is mucus, with or without blood, is indicative of duodenitis.

Enteritis.—Colicky abdominal pains extending in various directions, accompanied by unpleasant sensation of pressure, abdominal distention, diarrhea, loss of appetite and thirst, indicates that the patient is suffering from acute inflammation of the bowels.

Colitis.—While involvement of the colon, makes itself manifest by an increase in the diarrhea, the limitations of the pains and the sensativeness on pressure largely to the large bowel.

Sigmoiditis, Proctitis.—Colicky pains in the left iliac fossa followed by tenesmus and mucous blood-stained stools, are indicative of inflammation of the sigmoid flexure and the rectum.

Enterocolitis in Children.—While intense griping abdominal pains occurring during the summer months in a child under four years of age accompanied by constant vomiting and frequent watery discharges from the bowel, rapid pulse, high bodily temperature, and collapse, is symptomatic of enterocolitis.

Chronic Enteritis.—Recurring abdominal pain following errors in diet, unusual physical exertion, mental excitement, accompanied by abdominal distention, gurgling sounds when pressure is made on the abdomen, and diarrhea with or without tenesmus, is indicative of chronic intestinal inflammation.

Membranous Colitis.—Abdominal pain localized in the transverse or descending colon continuing for several days and occurring in a neurasthenic woman giving a history of constipation followed by the voiding from the bowel of strings of mucus or casts of large gut, is indicative of membranous colitis.

Fecal Distention of Cecum.—Abdominal pain and tenderness of mild character located in the right iliac fossa in an aged person of sedentary habits or in a child, who also complains of digestive disturbances, and who has a doughy sausage-shaped tumor in the cecal region is indicative of fecal distention of the cecum.

Impaction of the Feces.—Abdominal pain, accompanied by mild symptoms of intestinal obstruction and a feeling of weight, and distention in the right iliac region and tenesmus occurring

* Read at the Ninety-eighth Annual Meeting of the Medical Society of the State of New York, held at Albany, N. Y., January 26, 27 and 28, 1904, as a part of the Symposium on Abdominal Pain.

in elderly people of sedentary habits, is indicative of fecal impaction; the diagnosis being definitely settled by a local examination.

Lead Poisoning.—Severe abdominal pain, distention and tenderness associated with vomiting, constipation, followed by diarrhea, occurring in one who is also suffering from acute anemia and who has recently been exposed to the fumes of lead is indicative of acute lead poisoning. In the chronic form of the disorder, intestinal colic and a blue line on the gums, occurring in a lead worker, are the most important factors in making a diagnosis.

Primary Tuberculosis of the Intestines.—Colicky abdominal pains occurring in a child having enlarged mesenteric glands, moderate fever, irregular diarrhea and who is losing markedly in weight, are suggestive of primary tuberculous infection of the intestines.

Secondary Tuberculous Infection of the Intestines.—Recurring attacks of severe abdominal pain associated with alternating attacks of constipation and diarrhea, occurring in a patient having tuberculous involvement of the lungs and who also has a thickening of the tissues, or an elongated tumor in the right iliac fossa, are indicative of secondary tuberculous infection of the intestines. In both cases, the diagnosis being settled by the finding of the tubercle bacillus in the fecal discharges.

Tapeworms.—Abdominal pains occurring in an anemic person who is also suffering from nausea and diarrhea, but whose appetite is good, is suggestive of tapeworm; the diagnosis finally depending, however, on finding segments of the worm in the stools.

Intestinal Ulceration.—A continuous abdominal pain, associated with tenderness on pressure, always localized in the same spot, is symptomatic of intestinal ulceration. When the ulcer is located in the first portion of the duodenum, the pain is situated in the right hypochondriac region, radiates down toward the pelvis, and comes on about two hours after eating and usually occurs in an adult male, thirty to sixty years of age, who also passes blood with more or less frequency, or in a woman who has within a week or two suffered from an extensive burn. If a patient suffering from typhoid fever in the third or fourth week of the disease complains of increased abdominal pain in the hypogastric region associated with irritability of the bladder with pain extending to the penis, early perforation of an intestinal ulcer may be looked for, as these symptoms indicate extension of the inflammatory process.

Appendicitis.—A sudden abdominal pain at first referred to the epigastric and umbilical regions and later becoming localized in the right inguinal region, accompanied by abdominal distention, rigidity and tenderness on pressure, is symptomatic of appendicitis, especially so, when occurring in a young adult male, following unusual physical exertion, or in a female at or near the menstrual period, who are also suffering from constipation, gastric disturbance, a moderate amount of fever, irritable bladder and a rapid pulse. It must, however, constantly be borne in mind that as the location of the appendix varies the pain accompanying it does also and may be located in the right lumbar, lower epigastric or umbilical region, in this last case, it may sometimes even be to the left of the median line, instead of in the right iliac fossa. The tenderness on pressure ordinarily remains, however, at this point with a dart of pain to the umbilicus as has recently been pointed out by Alexander Lambert, as the attachment of the appendix to the cecum is fixed. Constantly recurring attacks of appendicular colic are probably due, as has been stated by Talamon, to violent and irregular contractions of longitudinal muscular fibers in the effort to expel mucus.

Obliterative Appendicitis.—A constant abdominal pain over McBurney's point, with tenderness on pressure, is indicative of chronic obliterative inflammation of the appendix.

Chronic Relapsing Appendicitis.—Recurring attacks of pain in the right inguinal region at varying intervals, occurring in an anemic and emaciated individual, who complains also of digestive disorders and constipation, is suggestive of chronic relapsing appendicitis.

Typhoid fever in its earlier stages is often mistaken for appendicitis, but this error may frequently be avoided by remembering that while in appendicitis the fever is usually moderate in degree, and the pulse rate high, the reverse is the case in typhoid fever, where the body temperature is high and the pulse rate low. A blood count will also be of service. Typhoid fever in its beginning having a low leucocytosis, while appendicitis has a high one.

A diagnosis of appendicitis should never be made until a careful examination of the patient's chest has been made, as has been pointed out by Richardson, for the writer has knowledge of a case occurring in the practice of another surgeon, where the patient gave a history of recurring attacks of appendicitis, complained of pain in the right iliac and umbilical regions had gastric distention, fever, rapid respiration, and high pulse rate, but, it being hot weather, the chest was not examined. The condition was diagnosticated as appendicitis and operation was decided upon. The operation proved that the patient had previously had attacks of the disease, but was not at that time suffering from the trouble and further investigation revealed the fact that the patient was really suffering from a right-sided pneumonia. Unfortunately the patient did not survive. It must not be forgotten that in some virulent cases of appendicitis we have a normal bodily temperature with a high pulse and rapid respiration rate.

External Strangulated Hernia.—Severe abdominal pain referred to the umbilical region, associated with a sudden and complete constipation, persistent nausea and faintness and collapse,

is suggestive of external hernia, and search should be at once made in the inguinal canal, umbilical and femoral regions, obturator and ischiatic foramens, perineum, rectum, vagina and the entire abdominal wall for ventral or lumbar hernia, not forgetting to examine the linea alba, for localized tumor or tenderness on pressure. The symptoms of internal strangulated hernia are of course those of distinct intestinal obstruction.

Intestinal Perforation and Obstruction.—Sharp recurring abdominal pain, increasing in severity, at first localized and then becoming general, followed by muscular rigidity and marked localized tenderness, vomiting, rapid pulse and respiration, prostration and collapse, is indicative of intestinal perforation, when associated with a history of any variety of intestinal ulceration, stab and gunshot wounds or severe contusion of the abdomen. Similar symptoms associated with constant and violent peristalsis, absolute constipation, more marked abdominal distention, occurring in a patient giving a previous history of external hernia, operation, peritonitis, tuberculous intestinal disease or tumor, is indicative of acute intestinal obstruction, or the obstruction may be due to an internal hernia, Meckels diverticulum, a long adherent appendix or Fallopian tube, or the paralysis following plugging of mesenteric vessels by a thrombus or embolism. The last condition may be suspected when a patient having a diseased heart or arteries, or pulmonary disease complains at first of severe general abdominal pain and tenderness, which is out of all proportion to the accompanying constitutional symptoms and whose constipation does not yield readily to treatment, or who passes a quantity of blood by the bowel. Unless the condition is recognized and the patient relieved promptly by the excision of the diseased gut, the general symptoms of obstruction and perforation already alluded to, soon follow.

In a case of this kind recently seen and reported by the writer the cause of the trouble proved to be due to the extension of the inflammation from a diseased appendix to the contiguous mesenteric vessels. The patient's symptoms were for the first two days of the illness those of mild recurring appendicitis, and were then followed by severe abdominal pain to the left of the median line, the pulse and temperature remaining practically normal for forty-eight hours longer, when symptoms of intestinal perforation manifested themselves and when the patient's abdomen was opened a few hours later, it was found to contain about a gallon of liquid intestinal contents and blood, a coil of the ileum about twelve inches long in a gangerous condition, black in color with a perforation the size of a five cent piece presented itself. The appendix was found acutely inflamed, especially its tip, which was bright red in color and adherent to the mesentery of the necrosed bowel. The report of the pathologist, Dr. Horst Oertel, was as follows:

"The portion of the small intestines shows deep hemorrhagic infiltration of all structures with edematous swelling, and simple necrosis of all tissues, it evidently progressing from the deeper portions to the mucous membrane. The vessels being very much dilated and thrombosed in one portion the size of a five-cent piece. Necrosis had so far advanced as to produce rupture of the gut. Immediately around the opening there was found necrotic tissue without inflammatory reaction."

In discussing the case just alluded to, and in referring to the character of the abdominal pain found in such cases, Dr. Alexander Lambert said that a patient of his, an intelligent physician, suffering from this condition, told him he felt as if every little capillary throbbed with pain.

It may be well to bear in mind that the patient generally rallies from the shock following perforation, and if the operation is performed within twelve hours the chances of recovery are usually reasonably good. A hypodermic injection of ergot and strychnine, with an intravenous injection of saline solution, may be used to rally the patient before the operation is undertaken with great advantage.

Hemorrhoids, Fissure or Anal Ulcers.—Severe abdominal pain during and after defecation, followed by discharges of a small amount of blood, occurring in a woman, the pain being referred to the vagina and the uterus, is symptomatic of hemorrhoids, fissure or anal ulcer. The diagnosis is completed by local investigation.

Intussusception.—A violent recurring abdominal pain, occurring suddenly in a healthy infant, accompanied by tenderness and passages of blood-stained mucus from the bowel and an elongated cylindrical abdominal tumor is indicative of intussusception.

Chronic Obstruction of the Colon.—Subacute intermittent symptoms of intestinal obstruction accompanied by tenderness on pressure, and the voiding of mucus tinged with blood by the bowel are indicative of chronic obstruction of the colon.

Volvulus of the Sigmoid Flexure.—Subacute symptoms of obstruction occurring in a male over forty years of age giving a history of constipation, the prominent feature of the disease being an extreme and rapid distention of the intestine, is symptomatic of volvulus of the sigmoid flexure.

Malignant Intestinal Disease.—Colicky abdominal pain occurring in a person advanced in life, having a history of obstinate constipation, associated with an increasing cachexia and anemia, accompanied by a hard nodular tumor which is tender on pressure, is indicative of malignant intestinal disease. The higher up in the canal the disease is located the more acute the symptoms, while, when it is located in the rectum, it is indicated by more or less tenesmus

brought on by or occurring during and following evacuations, the pain radiating down toward the loin, genitals and upper part of the thigh, accompanied by alternating evacuations of mucus, pus, blood and fecal matter.

Conclusion.—From what has already been said, it is clear that the chief value of abdominal pain as a diagnostic symptom in abnormal intestinal conditions, is not only to call the attention to the fact that the patient is suffering from an intra-abdominal disorder of greater or less severity, but also in the class of cases requiring surgical intervention for their relief, to indicate to the surgeon the locality of the trouble, hence, it becomes the duty of the physician in all cases in which severe abdominal pain is a prominent factor, to make careful notes of the patient's condition and symptoms when he first sees him, to refrain from the administration of narcotic and cathartic drugs, until a surgeon, when practicable, has also seen the patient, a diagnosis made, and a definite line of treatment decided upon.

It must constantly be kept in mind that a severe, sharp and persistent abdominal pain, almost invariably means peritoneal involvement, provided the chest has been carefully examined and its diseases excluded, and that sudden cessation of such a pain accompanied by a rise of pulse rate and increased frequency of the respiration with or without a lowering of the bodily temperature, usually denotes gangrene of the gut and its perforation. Many lives will be saved, and thousands of others made more comfortable when physicians generally come to recognize that in all cases of persistent abdominal pain of obscure origin, exploratory operations should be performed, for it has been the writer's experience that a cause always does exist when such a pain is present, and that it is usually found with ease when looked for; in other words, when in doubt operate, for, as Osler has wisely said, "The surgeon is often called too late, never too early."

55 West Thirty-sixth Street.

THE DIETETIC TREATMENT OF ARTERIOSCLEROSIS.*

BY THOMAS L. COLEY, A.B., M.D.,
OF PHILADELPHIA;
VISITING PHYSICIAN TO THE METHODIST EPISCOPAL HOSPITAL, ETC.

The object of this paper is the brief consideration of some of the cardinal points in the dietetic management of arteriosclerosis. The importance of regulating the manner of life and the diet of the patient with this affection is well recognized, but unfortunately not sufficiently emphasized in daily practice. In the iodine compounds and the nitrites we have at hand remedial agents of great value. The judicious use of these drugs is rational and proper, yet the treatment of a case of arteriosclerosis must not rest with drug administration, for, if it does, we are fighting against too great odds. We have failed to consider the strong probability that the constitutional effects of the quantity and quality of the food in which the patient habitually indulges will greatly modify, if they do not absolutely nullify, the physiologic action of our drugs.

Arteriosclerosis is a condition of degeneration of the arterial wall followed by fibrous hyperplasia leading to contraction and rigidity of the vessels and increase of blood pressure. It is not agreed among pathologists whether the media or intima is first affected. Thoma holds that the process starts in the media owing to the lessened resistance of this coat. The vessel in consequence becomes wider and the blood stream is slowed. By a compensatory process connective tissue develops in the subendothelial layers of the intima in the effort to restore the normal relation between the artery and the blood stream. Sansom states that the thickening of the vessel walls may begin in the internal coat, in the external coat, or that the process of fibrosis may even arise externally to the arteries altogether, but by its extension may involve these. Probably some cases of granular kidney have their origin in a proliferating change in the fibrous tissue external to the blood vessels, others in the blood vessels themselves. In lead poisoning, for instance, the initial nephritis is parenchymatous. We have strong evidence that in many cases the sclerotic changes are due to a soluble poison circulating in the blood. Let us consider for a moment the explanation of Sansom. In his first group of cases this poison acts directly upon the internal coat of the vessel; in his second group the channels are the lymphatics which are so abundant around the external coat; in his third group the distribution is through the lymphatics in the various fibrous tissues. Among the toxic causes giving rise to such a poison are syphilis, alcohol, gout, chronic lead poisoning, diabetes, chronic tuberculosis, and interstitial nephritis. There is another theory of the causation of this affection which holds that arteriosclerosis is not primarily a vascular disease but is the result of metabolic depreciation or perversion. The association of tissue degeneration, fibrosis and arteriosclerosis is almost invariable, though the exact nature of the relationship is at present unknown (Adler). It is well to recall that hereditary influences, especially syphilis and the constitutional tendency to gout and tuberculosis, play an important part in the development of arteriosclerosis in an early period of life, especially in the second and third decades. An anatomic peculiarity, congenital narrowing of the aortic system, gives rise to a tendency to the acquirement of many diseases and among these arteriosclerosis is frequently observed. J. Burke mentions that the arterial changes occur in these patients at a very early period as a consequence of the persistent high blood pressure. The clinical signs are pallor, a sense of constriction in the chest, dyspnea, cough

*Read by invitation before the South Branch Philadelphia County Medical Society, Sept. 25, 1903.

and expectoration. The left ventricle undergoes hypertrophy with dilatation and consequent insufficiency. The liver is found to be enlarged and there are edema and albuminuria.

A consideration of the question of blood pressure is of extreme importance. W. Broadbent has drawn attention to the fact that in many long-lived families the pulse-tension is low and the longevity is due to the fact that there is less strain upon the heart and blood vessels. High tension is also likely to be hereditary, commonly in association with diseases the result of or accompanying faulty metabolism, examples of which are gout and nephritis. Broadbent is of the opinion that high pressure is best treated by eliminants; and P. W. Williams, in discussing Broadbent's paper, emphasizes the fact that increased tension is probably intended for the purpose of eliminating toxic substances, and that the tension should be, as far as possible, let alone and elimination be aided by eliminative drugs and proper diet. We may complete our summary of the etiology of arteriosclerosis by stating that it may be induced by over exertion, either physical or mental, by overfeeding, and that it is to a certain degree physiologic in old age. We have seen from what is stated above that persistent high blood pressure is a dangerous forerunner of arteriosclerosis: and as a necessary principle to guide us in our treatment we must be familiar with those causes which lead to high blood pressure and endeavor to reduce their effects as far as possible.

The blood vessels are resisting elastic tubes; the resistance is always equal to the pressure within, hence blood pressure and arterial tension are equivalent terms. We speak of increased or diminished pressure or correspondingly of high or low tension. Blood pressure may be increased by quick action or increased force of the heart; by increased volume of blood and by those causes interfering with the normal movement of the circulatory stream, for instance by congenital narrowing of the aorta, by increased resistance from within or without the vascular system. The volume of blood is increased after meals or excessive drinking. As a consequence increased blood pressure and high tension result. This is controlled in health by the action of the vasomotor system, dilating the vessels and also by enlargement of the veins. When the quantity of blood remains normal and the capacity of the vessels is lessened from any cause as, for instance, cutting off a vascular area by ligation or obstruction, by narrowinig the caliber of the wall, as in arterial spasm, endarteritis, by disease of the kidney, contracting the lesser channels in the aortic circuit, or disease of the aorta causing obstruction to the outflow of blood—in all these conditions there results increased pressure or high tension (Musser). Nature makes the effort to reduce this tension by the action of the normal regulating vasomotor apparatus.

In our consideration of the etiology of arteriosclerosis we have dwelt at some length on the fact that continued high blood pressure, from whatever cause, whether due to the action of a poison circulating in the blood stream, or due to increased capillary pressure, if not corrected is bound to result in sclerotic arterial changes.

When we consider that the circulatory system in any, or all, of its parts may undergo sclerotic changes we are not surprised at the great number of clinical manifestations of this condition that may arise. Symptoms may develop in any organ or part as a result of the faulty circulation. As is to be expected those organs or parts which have most work to do and which in consequence demand the most blood are most frequently the seat of morbid changes. We would mention these in the following order: (1) The heart, (2) the nervous system, (3) the kidney, (4) the gastro-intestinal tract. We must recognize, however, that there are no hard and fast lines of involvement, that every case is a law unto itself; there may be localizing symptoms or simply a general breakdown.

For the sake of bringing out clearly the forces which are usually at work in these cases and for the further purpose of indicating our line of treatment, I shall mention a few of the typical classes of patients who present themselves for treatment. The proviso is made, however, that this classification is adopted merely for the purpose of convenience and that a particular case may belong to two or more of these groups, or not fit into any of them.

First, those cases occurring in young men who have been used to hard, manual labor and physical overstrain. These patients frequently complain of vague dyspeptic symptoms or, perhaps, cardiac discomfort. Very frequently they live irregularly and use alcohol to excess. Their muscular labor makes constant demands for increased blood supply and cardiac hypertrophy results. Sudden overexertions make frequent unusual demands for blood and the vasomotor system is finally unequal to adjust the blood pressure to normal; it remains constantly high. Valvular lesions, as well as dilatation of the heart, are frequently encountered.

Second, may be mentioned patients of plethoric habit—the obese, well-fed men of business or professional life. This class works with its head rather than its hands. As a rule these patients eat too much and exercise too little. There is complaint of gastric disturbance, often chronic constipation and, very usually, mental torpitude. The patient tells us that he finds himself unequal to his work, that he is forgetful, irritable, and less sure in his judgment than he has been.

Our third class is comprised of the ill-nourished, highly nervous individuals past the fourth decade in years. These patients have plainly visible and tortuous arteries. They are neurasthenic, introspective and hypochondriacal.

The fourth class might be included as a later stage of the second. Men of affairs not of nervous habit, suddenly seem completely changed in disposition. They often complain of insomnia,

palpitation, mental lapses, inability to center attention, and at times spells of syncope.

It is not within the scope of this paper to discuss the diagnosis of arteriosclerosis, yet it is but truth to mention the fact that it is not uncommon to see these cases wrongly diagnosed and, in consequence, wrongly treated. It stands to reason that the indication is to lower the blood pressure and spare the heart, yet stimulation and even the use of digitalis may be laid at the door of many a worthy practitioner in the very cases when the main indications are diametrically opposite.

In the management of arteriosclerosis we must consider the long course of the affection and the fact that the damage which has been done cannot be repaired. The physician's aim must be to arrest the process and thereby make it less likely that serious complications follow. The patient with arteriosclerosis, whatever his years, is to be regarded as an old man whose work in life must be of the lightest character and whose road must be made as smooth as possible. The laborer with this condition must find lighter work and, indeed, muscular work, in general, should be kept at the point of merely maintaining the cardiac hypertrophy and muscular nutrition. I am well aware that these indications are difficult of attainment, but nevertheless they are clearly outlined, and when once recognized very often much may be done. It may not be impossible for many sufferers to change their vocations to those whose duties are less arduous. When once our diagnosis is fully confirmed our advice should be emphatic. The picture of the final complications of arteriosclerosis—apoplexy, aneurism, angina pectoris, uremia—is rather less pleasant to contemplate than even the most radical change in a man's vocation and manner of life. What we have said refers especially to the class which do manual work; to those whose mental burdens are great, as in the responsibilities of a great business, we must be equally insistent. Frequent vacations in which the patient gets back to nature as closely as possible are not always unattainable, and it is often feasible to lighten the burden of one's mental responsibilities when the need is imminent.

The question of diet in general is one of far greater importance than I can hope to set forth to-night, but there is no condition in which it might be made the text of an excellent sermon with greater profit than in the discussion of arteriosclerosis. There is the same danger of overfeeding an adult that there is in underfeeding an infant. Unlike other animals, man has an extremely varied dietary. His gastro-intestinal tract is called upon to perform heroic work in the digestion of improper food as well as too much food. Most of the carnivora feed but once in twenty-four hours; in man, the stomach at best gets but a short rest. We have departed so much from primitive life in the development of our civilization and especially in the curtailment of exercise that elimination is accomplished with greater or less difficulty.

It is necessarily impossible in view of the manifold conditions by which we are confronted, to lay down hard and fast rules for the dietetic treatment of arteriosclerosis. The general indications, however, are clear enough and these must be so altered as to meet the needs of any given case.

Chemical action is the basis of all vital activity. In the performance of bodily functions energy is yielded in the form of work and heat. To supply this energy new material must constantly be furnished and transformed into assimilable material which is utilized by the economy. Certain waste products which remain are to be carried off. The new material is brought to the body in the form of food which must fulfil the conditions of being received into the body, transformed, stored up as potential energy, and capable of yielding on demand muscular work and heat (kinetic energy). Foodstuffs are made up of alimentary principles or nutrients and certain waste products. However great the varieties of foods, all contain but few proximate principles. A convenient classification divides these principles into organic and inorganic. Of the organic principles, some are nitrogenous, *i.e.*, the proteids and albuminoids. While others are as non-nitrogenous, *i.e.*, the carbohydrates and fats. The inorganic alimentary principles are water and mineral matters.

The important elements in foodstuffs are nitrogen and carbon. The essential waste products are urea and carbon dioxide. The materials which we eat and drink differ widely in composition from the tissues which they are intended to form or repair. This material is generally in an insoluble form and it is by the processes of digestion that food is so changed that it may be absorbed by the blood and taken up by the tissues of the body.

Water and the inorganic salts are not regarded as foods in the usual acceptation of the term. Since these substances are constantly, however, being lost in the excreta it is necessary that a fresh supply should be furnished to the body. Unlike the other foods water and the inorganic salts are capable of passing through an animal membrane by direct diffusion. They need no digestive action. A glance at the various chemical analyses of food will show that water in large quantities is contained in all and that salts are also present.

The proteids furnish the material from which the repair of old protcid tissue, as well as the development of new proteid tissue, is derived. It is known that the most important constitutent of living matter is the proteid part of its molecule, and for this reason proteid foods are an absolute necessity. Proteids contain nitrogen, while carbohydrates and fats do not contain this element. Therefore, proteid material alone must be supplied in order that new protoplasm be formed. In order to maintain the proper equilibrium of the body a mixture of the alimentary principles should be used; but without proteid

material, the inorganic salts and water, starvation would result.

The albuminoids resemble the proteids closely in their composition: gelatin is an example. They contain nitrogen and are of complex structure, but they cannot take the place of proteids in building up protoplasm. They act, rather, in the manner of the non-nitrogenous foods.

The carbohydrates contain no nitrogen. In this group we include the starches, sugars, etc. In their destruction in the body a certain amount of energy is liberated. The energy of muscular work and of the heat of the body comes largely from the destruction or oxidation of carbohydrates.

Fats, including the animal and vegetable oils, contain no nitrogen and their use in the body is practically the same as that of the carbohydrates. As sources of energy weight for weight fats are more valuable than the carbohydrates, but they are digested with greater difficulty.

Meats have a relatively large amount of proteid, or of proteid and fat, and a small percentage of carbohydrates. The vegetable foods are distinguished, as a rule, by the large percentage of carbohydrates and, with exceptions, by small amounts of proteids.

It is of great importance to know the nutritive value of the articles which make up our ordinary diet, but it is equally important to remember that these articles are not digested at the same rate or with equal completeness. It has been demonstrated that the proteids of animal foods are more completely digested than those of vegetables and for that reason the chemical analyses express more directly their food value. The relative value of various foodstuffs may be considered from the four points of view suggested by Hutchison: (1) Chemical. What percentage of each nutritive constituent does the food contain? (2) Physical. How much potential energy is it capable of yielding? (3) Physiological. How does it behave in the stomach and intestine? Is it easily digested, and to what extent is it absorbed? (4) Economic. Are the nutritive constituents which the food contains obtained at a reasonable cost?

1. Chemical analysis gives us the percentages of proteid material, carbohydrates, fats, etc., in a given part of the food considered and enables us to estimate the value of the food as a tissue former and work and heat producer. Satisfactory tables are to be found in all works on physiology and dietetics, and they should be consulted in framing a suitable dietary.

2. The changes which food undergoes in the body are essentially changes of oxidation and the amount of heat which a food is capable of yielding on complete combustion is taken as a measure of its value as a source of energy. The calorie is the standard of heat production and it is that amount required to raise the temperature of one gram of water one degree C. The kilo-calorie or the amount of heat required to raise one kilo of water one degree C. is usually employed for convenience in the measurement of the heat values of food. It is written Calorie with a capital letter in distinction to the ordinary calorie which is written with a small letter. The heat value of one gram of the three chief nutritive constituents when taken into the body tissues is as follows: Proteids, 4.1 Calories; carbohydrates, 4.1 Calories; fat, 9.3 Calories.

The method of applying the Calorie standard to a food is very simple. One has merely to multiply the percentage of proteid or carbohydrate which it contains by 4.1 and the percentage of fat by 9.2 to get the total Calories yielded by 100 parts of the food in question. Suppose, for example, that a specimen of milk contains in every 100 grams 2 per cent. of proteid, 4 per cent. of fat, and 6 per cent. of carbohydrate, then the Calories yielded by that quantity of milk would be as follows: Proteid, $2\times4.1=8.2$; fat, $4\times9.3=37.2$; carbohydrate, $6\times4.1=24.6$. Total Calorie value of 100 grams of milk 70.0 (Hutchison).

A man at full work must receive as a daily income about five per cent. of his body-weight (Waller).

Solid food	1 per cent.
Ogygen	1 per cent.
Water	3 per cent.

For example, a man who weighs 70 kilograms (about 160 pounds) must receive

Solid food	= 500 grams
Oxygen	= 700 grams
Water	=2,100 grams
Total	=3,500 grams

The 700 grams of solid food should contain about

140 grms. proteid
105 grms. fat
420 grms. carbohydrate
35 grms. salt.

For each kg. of body-weight the diet should contain two grams proteid, 1.5 fat, 6 grams carbohydrate, 0.5 grams of salt. A total of ten grams, or 1 per cent. of solid food. This amount of solid food should yield between 3,000 and 3,500 Calories. If we apply the simple rule given above in the estimation of the Caloric value of 100 grams of milk, we have

Proteid	140 grams$\times$4.1=	574
Fat	105 grams$\times$9.3=	976.5
Carbohydrates	420 grams$\times$4.1=	1,722
Total in Calories...		3,272.5

The amount of proteid in this diet is perhaps unnecessarily high. One hundred or one hundred and twenty grams would probably be sufficient. This abundant amount will be influenced by the age of the patient, his general health and the work in which he engages. A man at rest should receive one-half, or three-fifths of this amount. These points have been mentioned somewhat in detail for the purpose of enabling us to make a practical application of these facts.

It will be seen from the above that a man

weighing 160 pounds requires 1.6 pounds of solid food per day. If the patient is obese and is accustomed to overfeeding he takes much more food than even this most liberal standard allows. In all probability he exercises but little, has fatty, flabby abdominal walls and complains of digestive disturbances and chronic constipation. When we remember that the splanchnic nerves regulate blood pressure and that stimulation of these nerves increases blood pressure especially within the abdominal cavity, one of the contributing causes of arteriosclerosis in cases of this type becomes clear. Another factor also to be considered is that the constipation usually present leads to auto-intoxication which furnishes an additional means of increasing arterial tension by means of soluble toxins. It is evident that the amount of food must be reduced in these patients and that they should be forced to take moderate exercise and be relieved, as far as possible, of mental responsibility. There is danger in any reduction system, however, on account of the age of the patient and the tendency to fatty degeneration of the heart. Our object must be to produce a very gradual loss of weight and an increased muscular tone.

Other patients with arteriosclerosis may not be heavy feeders but the quality of the food they take will in all likelihood be found too rich in nitrogenous elements, and extractive matters. These are known to be eliminated with difficulty and to increase the blood pressure. In all cases of arteriosclerosis the proteids must be taken in moderation and meats, therefore, should be cut down but not totally excluded.

Foods rich in lime salts are contraindicated theoretically but it is doubtful whether the amount of calcium ingested can increase the amount assimilated for most of it is found to pass through the intestinal tract and may be recovered in the feces. Rumpf, of Hamburg, recommends, however, a diet poor in calcium salts; such as bread, fish, meat, apples and potatoes. He does not allow milk, eggs, cheese, rice, or spinach. Others permit milk and eggs and advise a restricted dietary composed largely of vegetables, cereals, milk and fruits.

In cases of arteriosclerosis it is always imperative to reduce the quantity of fluids taken whether alcoholic or non-alcoholic. The sudden entrance of a large quantity of fluid into the stomach produces an overdistention of the blood vessels, increases the work of the heart on account of the increased quantity of the blood; the blood tension is further also raised by the irritation of the splanchnic nerves. Tea, coffee and cocoa should be prohibited or taken in small quantities. These contain alkaloids which practically have an identical action on the nervous system; this action is one of stimulation resulting in a temporary increase of blood pressure. In addition they form uric acid, retard digestion, somewhat, and increase the work of the stomach. Milk when taken as a food should be drunk slowly and in small quantities, preferably at the time other food is taken. It is well to remember that while milk is a liquid food in the ordinary sense of the term, it is practically a solid food as soon as it reaches the stomach on account of the coagulation of the casein. The curd of the casein is much more readily broken up when the milk is taken with other food. Alcohol is to be prohibited absolutely, unless it is indicated on account of the failing heart. Alcohol is one of the soluble poisons which is recognized as a potent influence in causing arteriosclerosis. Now, there are cases in which the absolute prohibition of alcohol may be of no avail. The alcohol habit may have extended over many years and is not to broken; in such cases the patient should be urged to take small quantities of whisky or brandy or a good dry wine with his meals and to stop the use of malt liquors entirely. The excessive use of tobacco is supposed by some to predispose, if it does not actually cause, sclerosis of the coronary arteries. This statement, however, rests upon doubtful grounds. It is wise in these cases to urge the moderate use of tobacco, recalling its tendency to produce irritable heart and digestive disturbances.

The association of arteriosclerosis with interstitial nephritis and gout, either as a cause or a consequence, has been mentioned and it is interesting to note that the most approved methods of treating these two conditions depend in large part upon the hope of eliminating the dietetic causes of high arterial pressure. Von Noorden especially questions the utility of a milk diet in interstitial nephritis and advises the curtailment of liquids and the taking of small meals. The amount of proteid food must not be too greatly reduced on account of the necessity of maintaining a due degree of cardiac hypertrophy. In the last few years the idea that white meats, such as chicken, fish and veal, are preferable to the dark meats on account of their containing less nitrogenous extractive matter has been denied, and it has been found that the varieties of meat have no constant influence upon the composition of the urine or the amount of albumin which it contains. Indeed the amount of albumin is an index of the severity of the affection in the acute forms of nephritis alone. We know, however, that white meats contain less proteid than the dark and in our effort to reduce the nitrogenous food advantage may be taken of this fact.

In the treatment of gout we must control the amounts of food which yield uric acid, and it is known that foods rich in nuclein perform this part. We must avoid, then, liver, kidney, sweetbreads, and restrict the use of the ordinary meats. Tea, coffee, cocoa and meat extracts are also direct sources of uric acid. Hutchison, discussing the diet in gout, says: "On the whole, the belief seems to be gaining ground that the quantity must be attended to quite as much as quality, and that the best diet for the gouty is a spare one, containing only a moderate amount of carbohydrate and fat, and in which not too much

of the proteid is derived from animal sources. In the light of the above facts, it might be well to add that, so far as is compatible with healthy nutrition, the animal ingredients should consist mainly of milk and eggs." The free use of water is ordinarly recommended for gouty people as an admirable aid in the elimination of nitrogenous waste. Yet, unless the water happens to possess aperient or highly alkaline qualities, it is doubtful whether drinking largely does more than to dilute the urine without increasing the total output of urinary solids.

As an epitome of the necessary dietic restrictions for patients suffering from arteriosclerosis the following may be said: (1) The quantity of food should be greatly reduced, not more than one-half or two-thirds the general average for body-weight being required. This amount in detail should be estimated according to the general rules laid down. (2) The quality of the food is important. Proteid foods are to be reduced, but not excluded. Meat should not be taken more than once daily and then in small quantity. It should be our effort to see that the patient obtains well cooked food especially avoiding large amounts of fat or other substances difficult of digestion. Alcohol, tea, coffee, and cocoa, as well as tobacco, are to be forbidden or used with extreme moderation. Excessive water drinking, or drinking large quantities of any fluid must be curtailed. (3) The regulation of meals is important. Breakfast should consist of fruit, a cereal with cream and perhaps an egg, poached or soft-boiled. There should be an interval of five or six hours between breakfast and dinner, and the heaviest meal should be taken in the middle of the day. It is not advisable to place too many restrictions upon what the patient shall have for his dinner. It may consist of soup, fish, meat, and vegetables, but overfeeding is to be strenuously avoided. Between dinner and supper five or six hours should also elapse, and this meal must be light and consist, as breakfast, mainly of fruit and cereals.

In general, a comparatively dry diet is indicated and the patient should eat nothing between meals. Elimination must be kept at its maximum of efficiency and our hygienic regulations laid down in great detail and strictly enforced.

ENLARGEMENT OF THE PHALANGES IN RICKETS: A REPORT OF TWO CASES.*

BY JACOB SOBEL, M.D.,
OF NEW YORK;
ATTENDING PHYSICIAN TO THE DEPARTMENT OF CHILDREN'S DISEASES, AT THE BETH ISRAEL HOSPITAL DISPENSARY, NEW YORK CITY.

THE osseous changes and deformities associated with rickets, more especially those of the head, chest, wrist and ankle, are so generally known and so frequently observed as to render any extended mention unnecessary. A reference to many of the standard English, German and French text-books on pediatrics will show an adequate description of these pathological conditions.

It is quite different, however, with the description or even mention of the changes and deformities in the bones of the hands and feet. To judge from the accounts of rickets in these works, it would seem that physicians controlling a large material among the poorest elements of the population, seldom observe these deformities or, if so, fail to mention them in their discourses on the subject. Thus Henoch,[1] Jules Comby,[3] Baginsky,[4] Ashby and Wright,[5] Seitz,[6] Cheadle,[7] Rehn,[8] Senator[9] and others do not refer to them. Jacobi[2] makes the general statement that "the extremities suffer in different ways in all their parts—the epiphyses and diaphyses, the periosteum, and the epiphyseal cartilages." Monti[10] states that "only in severe cases do changes occur in the phalanges of the fingers and toes, and again[12] that "in marked instances of rachitis the phalanges show similar changes to those of the forearm." O. Vierordt[11] says "that apart from an abnormal mobility of the joints of the hand there are no characteristic changes in these parts." Fischl[16] is credited with the statement that "a constant change which I consider typical is rachitis of the phalanges of the fingers; which, in marked cases, appear olive-shaped." Holt[13] writes that "enlargement of the ends of the metacarpal bones or the phalanges I have seen in but two or three extreme instances." Koplik[14] states very explicitly that "the phalanges are sometimes the seat of the rachitic processes. In one severe case I found all the phalanges thickened in the diaphyses. This case bore a very close resemblance to dactylitis syphilitica, especially as there was pain on pressure." An excellent illustration accompanies this statement.

Such being the facts, I desire to record the history of two cases observed in my dispensary practice and to present photographs demonstrating the condition in question.

Case I.—David K., aged three years, born in Roumania. Father and mother alive and healthy; no history of abortions. Child was brought to the dispensary because of "general weakness" and inability to walk. Mother stated that delivery occurred at full term and was perfectly normal; the child was breast-fed until the end of the first year, the first tooth, an upper central incisor appearing at four months. At the ninth month the mother noticed an enlargement of the ankles and abdomen, and difficulty in breathing; at one year this enlargement had increased. Being extremely poor, no doctor was consulted; in fact, the visit to the dispensary was said to be the first to any physician. After the first year the diet was a mixed one; the deformities, however, increased until at the time of his visit examination showed the following: Head large and square, fontanelles and sutures closed. (Mother said that at two years the anterior fontanelle was as large as that of a "baby"). All teeth present. Chest narrow, rosary felt both anteri-

*Read at a meeting of the Eastern Medical Society, May 8, 1903.

orly and posteriorly; marked lateral thoracic depression, kypho-scoliosis to the left. Excessive enlargement of the wrist epiphyses, curvature of the forearms. Skin pale and soft, tongue not enlarged, abdomen protuberant and tympanitic. Liver palpable, spleen enlarged. Thickened ankles, moderate degree of bow-legs. Heart normal; lungs, few coarse râles; temperature 99.2° F. per rectum. Blood shows a moderate degree of leucocytosis and chloranemia. No enlargement of the metacarpal or metatarsal bones. Both hands presented the following picture (Fig. 1. Right hand): The first, second and third phalanges of all the fingers of both hands, and both phalanges of the thumbs were thickened. There was no pain or tenderness on pressure, no edema of the skin or enlargement of the joints. The phalanges of all the toes showed a palpable thickening, though to a far less degree than those of the fingers. This thickening affected the shaft and more particularly the middle, rather than the epiphyseal ends. In

Fig. 1.

Case I.—Rickets. Diaphyseal thickening of the phalanges. Enlargement of the wrist epiphysis.

other words the enlargement was distinctly in the diaphysis. The enlargement of the three middle fingers was more marked than that of the thumb or little finger.

After observing this patient the mother was questioned in regard to other children with the result that on the following day the second child was seen.

Case II.—Rosy K. (Fig. 2), aged four years, sister of previous patient. Breast-fed for one year; first tooth at six months. When the child was two years old mother noticed a marked deformity at the ankle and took her to a physician who said that she had the "Englische Krankheit," and advised the necessary hygienic, dietetic and medicinal regime. This child did not begin to walk until she was three years old. Examination showed a large head with closed sutures and fontanelles, narrow chest, rosary, lateral thoracic groove, kypho-scoliosis more marked than in her brother, thickened clavicles, spleen and liver palpable, pot-belly, heart and lungs normal. Distinct epiphyseal enlargement at the wrist and ankle; curvature of the leg and arms more marked than in her brother. The thickening of the phalanges of the fingers and toes (Fig. 2 and 3) was less marked than in previous case though still distinct. Here the enlargement was most evident in the first and second phalanges of the middle and ring fingers of the right hand and the index and middle fingers of the left. In this, as in the former patient, the phalangeal thickening of the toes was more evident to the touch than to the sight.

Fig. 2.

Case II.—Rickets. Showing characteristic deformities and curvatures of forearms and legs.

The enlargement of the phalanges in these two cases is due in all probability to a superiosteal cell proliferation with imperfect and delayed ossification. Unfortunately I was unable to procure skiagraphs of these deformities.

There can hardly be any question as to the rachitic nature of these enlargements, first because of the simultaneous existence of other symptoms and lesions of rickets, and secondly because of the absence of any syphilitic or tubercular history or stigmata. Against syphilitic dactylitis speak the

absence of history, the symmetrical involvement of all the larger joints as well as the fingers and toes, the lack of destructive inflammation after so long a time without treatment, the presence of cardinal signs and symptoms of rachitis and the absence of all syphilitic stigmata-eruption, scars, snuffles, keratitis. Syphilis, as a rule, involves one

Fig. 3.

Case II.—Rickets. Showing right hand with enlargement mainly in the first and second phalanges of the middle and ring fingers.

or several fingers and is usually not symmetrical; Taylor[15] remarks, however, "In one instance I have seen every phalanx of each hand swollen."

I am indebted to Dr. Martin W. Ware for the privilege of seeing a dactylitis syphilitica involving all the fingers of both hands.

Syphilitic bone lesions in many children appear as a rule very early in life and generally attack the junction of the epiphysis and diaphysis. When the periosteum becomes involved it presents irregular elevations or a boggy infiltration, rather than a uniform thickening as in these cases.

Fig. 4.

Case II.—Right and left hand. Left hand shows phalangeal enlargement mainly in the first and second phalanges of the index and middle fingers.

Against tuberculous dactylitis we have the absence of tuberculous history, the negative condition of the lungs, the lack of pain, tenderness, necrosis, suppuration or limitation of motion, and the existence of a symmetrical involvement.

Only one other condition might be mentioned in differentiation—clubbed extremities. In this condition the fingers and toes alone are involved, the head, chest and epiphyseal bone changes being absent; the terminal phalanges are most frequently affected and there are evidences of pronounced or prolonged pulmonic or cardiac disease.

It is true that in the two cases reported the rachitic manifestations were very marked. However, since my attention has been directed to the phalanges, I have observed several cases of rickets of not unusual severity in which some phalangeal thickening existed. *It is my opinion that this condition is very frequently overlooked owing to lack of attention to the hands and feet.*

I might say that both patients were given antispecific and thyroid medication for a long time without any visible effect upon either the general manifestations or the phalangeal thickenings. These cases are interesting, not only on account of the unusual situation and extent of the deformities and of the importance of a proper diagnosis, but also because they show that rickets occurs in breast-fed babies when mother's milk lacks the proper quality and quantity of ingredients necessary for the growth and development of the child. This is a fact too often overlooked and occurs in my experience more frequently than is generally supposed.

I would venture to suggest that these deformities be designated as rachitic dactylitis, partly for the want of a better term to express the condition, and partly because even at this late day authorities disagree as to whether the "nervous (Tedeschi), alimentary (Trousseau, Guerin, Glisson), modified alimentary (Jacobi, Baginsky, Comby), season (Kassowitz, Schmidt, Alexander), infectious (Chaumier), or thymus gland theory (Friedelben, Mendel)" explains the symptoms and lesions of the disease. Since most are agreed that the bone changes are accompanied by hyperemia, dactylitis may not be so exaggerated a term.

Shortly after reading the foregoing before the Eastern Medical Society, I was very much pleased and interested to note a similar contribution by Dr. Rudolph Neurath in the *Wiener klinische Wochenschrift,* of June 4, 1903. This author states that his experience in a large series of rachitic patients has shown that a positive diagnosis of this affection can be made *par distance* from a peculiar deformity of the phalanges of the fingers which gives the bones a spindle shape. He very properly remarks that the middle part of the bone is thickened and that the region of the articulation is normal and appears as if sunken between the enlarged phalanges.

Radiography has demonstrated that the enlargement is periosteal. This phalangeal hypertrophy was observed by him only in severe cases presenting enlarged epiphyses and rosary. Only in rare instances did he observe any enlargement of the toes; when present it was very slight. He comments upon the lack of medical literature in reference to this part of the subject and quotes no less an authority than Kassowitz, as saying

that "alterations of the metacarpal bones and phalanges are rare and absent as a rule even in severe cases."

1828 Madison Avenue.

TREATMENT OF PNEUMONIA.

BY DELANCEY ROCHESTER, M.D.,

OF BUFFALO, N. Y.;

ASSOCIATE PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE, UNIVERSITY OF BUFFALO, BUFFALO, N. Y.

The recognition of the fact that pneumonia is not a local disease of the lungs but an acute infectious fever with its most pronounced anatomical lesions in the lung, gives a basis for the rational treatment of the disease.

In all infectious diseases we recognize a local lesion—usually situated at the point of entrance of the infecting organism—and a toxemia of more or less pronounced intensity varying greatly in different cases.

The toxic condition of the blood impairs the nutrition and interferes with the normal functioning power of the several tissues of the body. Next to the lung, the organs most seriously attacked in pneumonia are the heart and the kidneys. In all cases of pneumonia the pleura is involved in some degree, sometimes bearing the brunt of the attack, even developing a purulent exudate. The lesion in the lung is primarily a congestion rapidly passing to the stage of fibrinous exudate into the air space and round cell infiltration in to the pulmonary tissue, ending in resolution or desintegration.

A brief review of the clinical course of a favorable case shows us the initial chill; the high temperature; the increased frequency, full volume, high tension and normal rythm of the pulse; the coated tongue; the anorexia; the sluggish liver and inactive bowel; a kidney not functioning properly; the diminished excretion of chlorides; the presence of albumin, and usually casts in the urine; the more or less pronounced nervous symptoms; the cough, the rusty sputum, the dry, hot skin; the flushed face of slightly dusky hue, and the leucocytosis. For a week or ten days these symptoms persist, the most important change occurring in the increasing frequency of respiration and loss of the tension and sometimes change in rhythm of the pulse.

At the end of this period there occurs a profuse sweat, the temperature falls, the respiration becomes less frequent, the pulse improves in rhythm, the patient falls into a quiet sleep and awakens refreshed and well. Sometimes a watery diarrhea accompanies or takes the place of the sweat. If the case does not go on to recovery or dies before the time of the crisis, death occurs either from the intensity of the toxemia or from interference with oxygenation from involvement of too great extent of lung or from some complication.

The chief cause of death in pneumonia, exclusive of complications, is failure of the circulation through degeneration of the myocardium. Several factors enter into the causation of this myocardial degeneration, namely, the toxemia of the infection acting directly upon the muscle fibers; the same cause active in the general system and producing an increase in the arterial tension throughout the body, thus making harder work for the myocardium of the left heart already suffering from toxemia; the morbid changes in the lung causing obstruction to onflow of the blood from the right heart, thus throwing harder work upon the right myocardium also suffering from the toxemia. The amount of pulmonary involvement would be, of course, a decided factor from this point of view, as well as from that of interference with oxidation, too great an interference with this function producing death.

Sometimes death occurs from the effect of the toxemia upon the brain; wild maniacal delirium wearing the patient out or a low, muttering delirium ending in coma and death. Sometimes the kidney bears the brunt of the attack and uremia is added to the toxemia of the infecting organism.

Occasionally the gastro-intestinal tract is most seriously involved, and there occurs a violent diarrhea or a marked fibrinous inflammation of the lining mucous membrane.

The most common and serious complications of pneumonia from which death may occur are meningitis, pericarditis, endocarditis, nephritis and empyema. These, however, will not be considered in this discussion, which is limited to the treatment of pneumonia.

To plan a rational mode of treatment in an acute infectious disease it is important to note the mode of recovery and the usual modes of death, and to establish such procedures as will tend to promote the former and prevent the latter.

Such a plan, in the treatment of pneumonia, may be divided into the following general heads: (1) To relieve toxemia; (2) to prevent failure of heart; (3) to meet complications as they arise.

For the relief of toxemia, there are three natural avenues of excretion by which poisons may be carried off; these are the kidneys, the bowel and the skin.

In all cases of pneumonia we have inflammatory involvement of kidney to a greater or less extent. The attempt to stimulate to excessive functional activity an organ in a state of acute

inflammation is worse than useless, so the use of stimulating diuretics is positively contra-indicated.

The bowel and the skin remain and nature has shown by the profuse sweat at crisis and the occasional critical diarrhea that these are the avenues that are preferred.

So our first indication in treatment, the relief of toxemia, may be met by induced sweats and mild catharsis. The mild catharsis is best produced by the administration of calomel at the onset of the disease to be followed by the use of a saturated solution of Epsom salts in moderate dose daily. The calomel dose may be repeated occasionally as the indications arise. The sweating is best and most easily induced—not by the administration of drugs—but by the hot mustard footbath scientifically given in bed with no disturbance of the patient. As much depends upon the proper method of giving this bath and as I have seen failures through lack of this knowledge, I shall describe the procedure in detail.

The patient, in a nude condition, lies between blankets with his knees flexed, his feet in the tub which has been introduced under the upper blanket, the long axis in the line of the patient's body and legs; another blanket passes from under the tub up over the end and over the knees of the patient; two to five blankets or a fewer number of blankets and a rubber sheet are then placed over the patient extending from the neck of the patient over the foot of the bed and tucked in around the foot-tub and side of the patient. The tub at first is filled half full of hot water in which a heaping tablespoonful of mustard has been dissolved—from time to time during the bath more hot water is added, care being taken that the water is poured against the side of the tub and stirred in by the hand of the nurse, in order to avoid burning the patient's feet. The bath is kept up from thirty to forty-five minutes according to the amount of sweating produced. During the administration of the bath cloths wrung out of ice water are kept constantly on the head of the patient. This sweating in connection with the stimulation to be referred to later, is, in the opinion of the writer, the most important of the general therapeutic measures.

Another measure of value in preventing further bacterial invasion is the frequent and thorough cleansing of the mouth with a mildly antiseptic solution. I think this a measure of considerable importance, as we know the pneumococcus is present in the mouth in considerable numbers.

While attempting to get rid of toxins by these means, it is important to put and keep the patient in the best possible condition to resist and overcome the toxemia that is present. For this purpose care should be exercised in the selection of a proper diet. This should be fluid and so far as possible should be sterile, so that no new poisons may be introduced. A large amount of pure water should be administered so that there may be plenty of fluid to flush the excretory organs. It is best administered in small amounts at short intervals.

Moreover the patient should be placed in the best ventilated room possible to secure and one to which there is free access of direct sunlight. The free catharsis and profuse sweating, besides aiding in elimination of toxins, tend to dilate the capillaries, thus relieving the arterial tension and getting rid of the capillary resistance to the onflow of the blood, making the work of the heart easier. One of the serious dangers we have seen is over distention of right heart. This can often be prevented by careful study of the lung condition as well as the state of the heart itself and the prompt institution of the procedure indicated. A careful physical examination of the chest should be made by the physician at every visit. In this way he can tell when congestion is beginning in any part; and vigorous local treatment will in many cases prevent the further progress of the morbid process. As soon as a portion of the lung is shown by physical examination to be in a state of beginning congestion, the prompt and thorough application of leeches, wet cups or dry cups over the part, will often stay the process there; or if it does not stop it entirely, will delay its progress twenty-four or forty-eight hours and give an opportunity for the clearing up of any previously involved portion of lung. My preference is for leeching or wet cupping. If dry cupping is resorted to, it should be very thorough, the skin and subcutaneous tissue rising up in the cup to as great a height as possible and turning blue or purple while there. The cups should be left on for a half hour and the process repeated every four to six hours. I have seen, post mortem, the direct anatomical evidence of the local value of this procedure, when thoroughly done. During the intervals between the applications of the cups the chest should be covered with a light woolen jacket. The poultice jacket should be relegated to the dark ages.

With ice applications I have not produced the relief of congestion desired. If, in spite of these local measures to relieve congestion, the process still persists and we begin to have evidence of overdistention or right heart, such as increasing cyanosis, the pulse losing its tension and becoming small and sometimes irregular, the liver enlarged, the veins pulsating and the area of cardiac dulness increasing chiefly to the right, whether a murmur of tricuspid insufficiency is present or not, prompt relief can usually be obtained by the withdrawal of 8, 10 or 12 ounces of blood from the median vein of the forearm. This procedure may be repeated several times if need be in the course of the disease. The procedure is of value both for its local effect in relieving the right heart distention and also for its general effect in withdrawing a decided amount of toxic material. At this time a little digitalis, given with due regard to its physiological effect, may be of decided value.

After the withdrawal of blood, and in cases in which heart failure is imminent without evidence of right distention, the subcutaneous injection of

normal salt solution has on several occasions proven of inestimable value. The use of the salt solution by rectum has also been of value, but of course does not give the prompt result that the hypodermic administration does. Whether the value of the procedure is dependent upon the restoration of bulk to the blood after the relief to the right heart has been obtained or whether the salt itself is of value, is worthy of investigation, the fact being established that in several cases that have come under my observation—in one of them three times—the administration of the salt solution certainly had a marvelous effect in averting an evidently impending death.

If more than one lobe is involved the regular administration of pure oxygen gas at stated times, shortening the interval and prolonging the duration of the administration if cyanosis persists or increases, or if the frequency of breathing progresses to dyspnea, has proven of undoubted value in a number of cases.

While these procedures to relieve the toxic condition and the local obstruction to the pulmonary circulation are being carried out, direct stimulation of the heart is of the utmost importance and should be begun as soon as the diagnosis is made and not delayed for the appearance of symptoms indicating cardiac failure. For this purpose our reliance should be placed upon strychnine, alcohol and ammonium corbonate or aromatic spirits of ammonia.

As soon as the diagnosis is made the strychnine should be begun in doses of 0.002 gram at four to six-hour intervals as indicated. The interval may be shortened and the dose increased as symptoms which call for such increase in dose appear. As much as 0.004 gram every two hours may be given hypodermically with the best results.

Next to strychnine, alcohol is our best stimulant. Nevertheless, in some cases it seems to produce decided cerebral disturbance, particularly in those addicted to its abuse. In such cases ammonium is a most useful substitute. These drugs are usually well borne by the stomach if combined with liquor amonii acetatis and administered in mucilage or milk.

In case of sleeplessness and restlessness chloralamid, chloral, Dover's powder, morphine and hyoscine hydrobromate are to be recommended in the order named; though with the thorough attention to the relief of toxemia by keeping the bowels and skin active, it is seldom that recourse to hypnotics is necessary.

To refer in any detail to the third indication in treatment, viz., to meet complications as they arise would carry me far beyond the scope of to-day's discussion; but I desire to say that under the eliminative supporting treatment outlined complications are rare.

Before closing I wish to utter a protest against the treatment of pneumonia by large doses of digitalis in the early stages of the disease as irrational and unscientific, being based on a wrong conception of the nature of the disease.

If our conception of the infectious nature of pneumonia is correct, by the time the chill has taken place the disease is established, and any efforts to jugulate the disease by the use of remedies employed to overcome or prevent pulmonary congestion are most certainly misdirected; for preventing the change in the lung—and it is doubtful if the digitalis treatment can accomplish this—certainly will not overcome the toxemia; two of the most serious cases of pneumonia that have come under my observation have had no pulmonary involvement demonstrable by physical signs.

The treatment of pneumonia by the pneumococcus antitoxin is the natural and rational plan from the recognition of the infectious nature of the disease, but so far the attempts to produce a reliable antitoxin serum that will preserve its antitoxic powers have not been entirely successful, and consequently there are very great variations in the reports as to the results obtained by its use.

I have recently had an experience that convinces me of the utter valuelessness of the antipneumococcic sera that are on the market and I feel sure that until we obtain a true antitoxin for pneumonia such as we have for diphtheria, we will get our best results by recognizing the essentially toxic nature of the disease and treating it along the eliminative supporting lines here suggested which may be briefly summarized as follows:

1. The sustaining of the metabolic processes of the individual by the administration of easily digested or predigested foods in small quantities at stated intervals, the administration of large amounts of pure water for eliminative purposes and the administration of oxygen gas by inhalation whenever the absorbing surface of the pulmonary mucosa is involved to such extent as to interfere with proper metabolic oxygenation.

2. Elimination, (*a*) by the liver and bowel through the vigorous use of calomel and salts; (*b*) by the skin through sweats induced by external heat; (*c*) through withdrawal of blood when indicated by right heart distention.

3. Stimulation of heart by strychnine, alcohol or ammonium carbonate, and in suitable cases by the subcutaneous injection of normal salt solution.

4. The local treatment of the lung by leeching, wet cupping or dry cupping as indicated.

In a former paper on the same subject, presented to the Section on Therapeutics of the American Medical Association, in June, 1901, published in the *Journal of the American Medical Ass'n.*, Nov. 9, 1901, I reported 168 cases treated according to the plan advocated. These cases are retabulated here:

Onset.	Termination.	Result.	Age.	Crises, Complications, etc.

1, 19,	2, 14,	"	40	Crisis tenth day; double pneumonia.
1, 21,	2, 12,	"	50	
1, 30,	2, 1,	Died,	46	Alcoholism; nephritis; entire left lung.
2, 21,	2, 27,	"	45	Double pneumonia.
3, 13,	4, 1,	Recovery,	49	Crisis seventh day.

There are in this report 168 cases with 21 deaths. Of those that died five had been sick a week or more before treatment was instituted, and so can not fairly be considered, two suffered with chronic nephritis, one had asthma and a dilated heart as well as being 89 years of age; one had typhoid fever as a complication and two entered the hospital with delirium tremens, no history obtainable as to the length of illness and died in less than 48 hours. If these cases are excluded, as I think they fairly may be, it reduces the number of cases to 157 and the deaths to 10, giving a death rate of 6.33 per cent. I have now to add to that report the following cases:

Onset.	Termination.	Result.	Age.	Crisis, Complications, etc.
5, 20, '01,	5, 31, '01,	Recovery,	35	Crisis third day; mitral obstruction.

1, 30,	2, 21,	"	56	Crisis ninth day.
8, 31,	9, 30,	"	50	Crisis tenth day.
8, 31,	9, 10,	Died,	52	None.
7, 28,	9, 3,	"	54	Empyema; operated; two distinct pneumonic attacks with crisis on seventh and ninth days; nephritis.
10, 10,	10, 18,	Recovered,	44	Crisis fifth day; mitral insufficiency; glycosuria; entire right and lower lobe left involved.

The cases occurred in the service of Dr. Chas. G. Stockton, whose assistant I am, in the Buffalo General Hospital; in my own service in two other hospitals in Buffalo, and in my private practice. Forty-two cases are included in this report. These added to the 158 previously reported make a total of 200 cases with 14 deaths, a death rate of 7 per cent. An analysis of these fatal cases shows that five were over fifty years of age, being respectively fifty, fifty-two, fifty-four, sixty-seven and eighty-nine years of age; that one was alcoholic, three had pericarditis as a complication, one being purulent pericarditis, and the other three were cases of severe double pneumonia. If I include every case that has come under observation it makes a total of 210 cases with 25 deaths, a death rate of 11.4 per cent.

In the last edition of Osler's Practice it is stated: "The careful and thorough analysis by C. N. Townsend and A. Collidge, Jr., of 1,000 cases, at the Massachusetts General Hospital, shows that when all fatal cases over fifty years of age were omitted and those patients who were delicate, intemperate or the subject of some complication were excluded, the death rate was a little over 10 per cent."

This is the same death rate that I have, without excluding any cases whatever. If the same classes of cases were omitted from my report it would reduce the number of deaths to five and the death rate to 2.5 per cent.

As these cases are taken from both private and hospital practice, most of them being hospital cases, and not from a picked practice, I feel that I am justified in the conclusion that better results can be obtained from the method advocated than by any other plan of treatment of which statistics have come to my notice.

THE SANITARY ASPECT OF FOOD PRESERVATIVES.

BY R. G. ECCLES, M.D., PH.AR.D.,

OF BROOKLYN, N. Y.;

MEMBER OF THE AMERICAN CHEMICAL SOCIETY; FELLOW OF THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE; MEMBER OF THE AMERICAN ANATOMICAL ASSOCIATION, ETC.

If an Egyptian fellah were offered as a gift one of our finest American steel plows, on condition that he abandon the use of his native one-handled, wooden plow, he would reject it with contempt. If asked if he was prejudiced against steel plows he would assert that he was not but would insist upon claiming for his wooden plow points of superiority over the former that made the latter immensely better. If foreign merchants should endeavor to push the sale of steel plows in that country there can be little doubt but that an organized effort would be established to suppress their use. So thoroughly fixed in human nature is the conservative instinct that it would be surprising to find any new and really good thing that did not meet opposition from some quarter. Food preservatives, like plows, have been in use from time beyond memory and yet recently introduced ones are subject to bitter opposition from people who dislike any change in food products. Like the Japanese woman who said, "Oh how disgusting" when told that Americans drank milk from cows these people have a sense of fear or disgust at an innovation which they dislike. In a prize essay on Preventive Medicine, lately published, the author says: "The use of chemical preservatives in food is to be prevented by stringent legal enactment." The author evidently intended to say "*modern* chemical preservatives" and "*ought* to be prevented" but in his haste got his meaning obscured. He surely did not intend to have laws forbidding the use of sodium chloride, acetic acid, or ethyl alcohol. These chemicals are so thoroughly established in popular favor, for this purpose, that any effort at stopping their use would be as futile as trying to sweep back the Atlantic ocean with a broom. When the term "chemical" is attached in this way to food preservatives it is because the author thinks it carries an opprobrious sting, forgetting that the old-fashioned preservatives are as much chemicals as are the more recent ones. The constituents of vinegar, salt, alcohol and smoke that render them antiseptic possess no superiority over the articles which biased people wish suppressed by law. Table

salt, the one most commonly used as a preservative of meat, has more serious drawbacks than its recent substitutes. In the first American edition of Wagner's Chemical Technology (p. 795) we are told that "salt, however, not only withdraws water from meat but also, as has been proven by Dr. Liebig's researches, some of the very best and essential portion of the juices of the meat, including albumin, lactic and phosphoric acids, magnesia, potash, kreatin and kreatinin. Hence it is clear that unless these substances are in some way or other added to the salted meat, its use as food for a lengthened period cannot fail to become injurious to the system, and it is surmised that scurvy is due to this condition of salt meat." Dr. Burnet declares (Wood's Med. and Surg. Monographs, Vol. XI, p. 598) that "Experience is not wanting to prove that cases of scurvy are, in the absence of complications, rapidly cured by dietetic means." He also informs us that of late years the number of cases of this disease has very markedly decreased. The decrease, it is important to note, is coincident with the adoption of modern preservatives. As barreled, corned beef, salty salt bacon and brine-preserved fish have grown into rare commodities, scurvy has diminished in intensity and frequency. Osler tells us (Practice, p. 393) that "the salted sturgeon used in parts of Russia has sometimes proved fatal to large numbers of persons." We thus see that besides scurvy there are other dangers attached to the use of salted foods. Salt is so poor an antiseptic that bacterial invasion of food is a danger to be counted with. In a quite extensive epidemic of pleuropneumonia that occurred in Middlesbrough, England, mentioned by Allbutt (System of Medicine, Vol. III, p. 789) we are told that "the investigations of Dr. Ballard clearly traced the source of the epidemic to the use of American (salted) bacon. . . . This bacon was proved to be poisonous to animals fed with it, and lung lesions were produced."

In some experiments performed by Prof. E. K. Dunham, of Bellevue Hospital Medical College, for Dr. E. L. Keyes, of New York, (Trans. Cong. Amer. Phys. and Surg., Vol. III, pp. 163, 164) it was found that while one part of salicylic acid in 960 parts of solutions would kill *Staphylococcus pyogenes aureus, Streptococcus pyogenes,* and *Bacillus coli communis* in two minutes one part of sodium chloride (table salt) in three parts of solution made not the slightest impression in ten minutes and in one experiment they were alive and vigorous in twenty-four hours.

Is it then any wonder that bacteria can thrive in salt while salicylic acid as a preservative is so much superior? These experiments did not show how very much superior the acid may be since far more acid was used than enough to produce the same feeble effects as did the salt. They merely show that the acid is far more than 320 times as potent as the salt. They also demonstrated that the salicylic acid is immensely safer to use than salt, so far as the effects, power for power, are upon the consumers. One can safely swallow, without the slightest inconvenience, 20 grains of salicylic acid, but we would pity the human being that ventured upon using at a single dose 6,400 grains of salt.

Here we might add that in spite of all the hue and cry of interested parties against salicylic acid that in an examination of every work on medical jurisprudence and toxicology found in three large libraries, one of them being an exclusively medical library, not one contained any reference to death from this substance. The works of Herold, Clarke Bell, Woodman and Tidy, Blyth, Reese, Hamilton and others were among those consulted. They showed deaths from tartaric acid, citric acid, acetic acid, from overdoses of ethyl alcohol, etc., but not one from salicylic acid. Evidently Prof. Hobart A. Hare had a somewhat similar fruitless hunt in getting together material for his article on salicylic acid in his Practical Therapeutics, or his Boylston Prize Essay of Harvard University for he tells us that so far as this acid is concerned "it is worthy of remark that very few deaths have taken place" (p. 343). Cushny, in his Pharmacology and Therapeutics, third edition (p. 423), tells us that it "is poisonous only in comparatively large quantities." On page 31 of Blyth's work on "Poisons," 1884, a table is given of all deaths from poisons in Great Britain for ten years in which tartaric acid, acetic acid and alcohol show rates of 12 to 17 deaths in each ten thousand of population but not one for salicylic acid or any other modern preservative.

With this array of facts what can be thought of those who strive to create terror in the public mind against so decidedly useful an article? Why seek to suppress an article that has a showing so clean that it is almost impossible to find a record of a death from it and yet complacently permit baking powders to be sold, without let or hindrance, when tartaric acid has killed so many? Why permit people using vinegar when acetic acid counts its deaths by scores or citric acid when its record is nearly as bad? It may be said that the latter are not used in concentrated form and they are usually consumed in the form of their salts. But this is equally true of salicylic acid. It is as senseless to condemn the use of salicylic acid, as diluted in food, as it would be to make a law, forbidding any ones selling lemons to the public. Citric acid is poisonous, it has killed scores, it is not a normal constituent of the body, it impairs digestion in its salts, and against it can be urged most of the stock arguments opposing food preservatives. Experimental evidence as well as the testimony of the results of use on millions of human beings both conspire to demonstrate the harmlessness of modern food preservatives, in the quantities required for such a purpose, and, because few have cared to battle with conservatism, they have been mercilessly and senselessly condemned. Immense as is the consumption in all parts of the

world not a single death has ever been recorded against their use in this capacity. Nor has the first case yet been found where deaths from foodstuffs protected with salicylic has been reported. Unprotected food, canned foods, that it is fair to assume were pasteurized or had been treated to high temperatures in an attempt to sterilize, salted foods, smoked foods, and dried foods have been fairly proven guilty of causing death. With so many people opposed to the use of salicylic acid in foods it is pretty certain that if any of the reported cases of meat, canned fish and other poisonings had contained it there would have been no hesitancy in telling this fact. Allbutt tells us that in the epidemics of food poisonings he had referred to one important feature "is that the outbreaks almost invariably occurred from food which had been prepard a day or so before being eaten—as if the infective micro-organism had gained access to the food after it had been cooked." (System of Medicine, Vol. III, p. 790). Anders speaks of mince meat, "warmed over" and carelessly kept kitchen salad as having caused "violent symptoms of poisoning" (Practice, p. 1,219). If these authors are reliable—and they are among the best in the world of medical science—then pasteurizing and sterilizing of food does not save the public from danger. If deaths and sufferings from severe food poisonings occur from kept-over food how can anything short of treatment with reliable preservatives save the careless public? If multitudes have been killed and other multitudes tortured in a most agonizing manner by the use of unprotected foods and not one soul has ever been shown as a sufferer from modern protected foods where is the wisdom in passing laws forbidding the use of protectives?

Is there any evidence in vital statistics of the ill effects of the rising tide of chemically preserved foods. The millions of tons daily consumed in all parts of the world should give some evidence of bad effects, if there are any. Places that consume most should show the highest average death rate in diseases of the intestinal tract. Have there been any signs of reduced public vitality during the years in which the consumption of preserved foods has been on the increase? Why do not the enemies of food preservatives consult such statistics and give us the figures that prove their contention instead of dealing in bald assumptions? Let us see if we can find out. The use of food preservatives of the condemned kind has been growing with more than tropical vigor for over thirty years. It is common knowledge that during the same time public health has been improving in a somewhat similar manner. There is then nothing in this that favors the idea that modern chemical preservatives are bad. The coincidence in time of the improvement in public health and in the increased use of preserved foods is remarkable. The improvement may have been in spite of the use of the preservatives but if it has the preservatives could not have seriously impaired the disease resisting power of the millions who have used them or the epidemics of influenza, and other contagious diseases, should have cut a deeper swath. The fact that the germs of such diseases, after gaining lodgment in human bodies that should have been weakened in resistance, did not decimate the population, as measles decimated the Fiji Islands, should be taken as some evidence that the theory of such weakening cannot be true. In 1886 the chemist of the Department of Health of the City of Brooklyn, N. Y., appealed to the Commissioner for the right to make raids upon brewers for using salicylic acid in their beers (*American Analyst*, April 1, 1887). He said: "I am of the opinion that it is time that the addition of salicylic acid to articles of food receive a check at the hands of sanitary authorities. I have made examinations of several different kinds of bottled beers manufactured and sold in this city, and have found a number of them to contain salicylic acid. The list examined contained some of the Western beers, which were also found to contain it. I would respectfully recommend that some action be taken by this Department toward the prohibition of this injurious adulteration." In this report we probably have the beginning of the systematic raids against food preservatives that have been going on in this country ever since. It is quoted by the chemist of the Department of Agriculture (Bulletin 13, p. 301) as "a very strong argument in favor of prohibiting entirely the use of this preserving agent." The Brooklyn chemist got the right to check the use of this agent and used that right. What were the results? Did the health of Brooklyn improve? In 1886 the death rate in that city was 22.5, in 1887 it rose to 23.5, in 1888 to 24.0, in 1889 it kept to 23.7 and in 1890 it made another ascent to 24.5. Here we see a steady increase in the death rate during the very years in which the raid was kept up. It is true that the raid may have had nothing to do with raising the death rate but it is equally true that these figures do not prove that the raid did the people of Brooklyn any good. During those same years Philadelphia allowed salicylic acid to be used in the beer of its citizens and the death rate was 22.1 in 1887, 20.3 in 1888, 20.0 in 1889 and 20.7 in 1890. Boston, that like Philadelphia, failed to make a crusade against salicylic acid, showed a death rate of 23.9 in 1887, 23.7 in 1888, 23.3 in 1889, and 23.7 in 1890. That the death rate should rise in the city which sought to suppress the use of salicylic acid and either sink or remain stationary in the two neighboring cities of about equal size is, to say the least, peculiar, and that peculiarity is emphasized when we learn that the larger city of New York, with only a river to separate it from Brooklyn, had a sinking death rate during the same years.

A study of the vital statistics of the United States as found in the Report of the Twelfth Census, published in Vol. III, 1902, gives us some highly interesting figures in connection with this subject. If the opponents of food preservatives have not taken the pains to look

into this part of the subject the writer would earnestly commend it to their attention. Here we find the unbiased report of the results of a trial of the effects of preservatives on Eighty Millions of people. This is certainly a much larger "poison squad" than Dr. Wiley ever could get under his supervision. Let them turn to page *227* and look at the table giving the death rates per 100,000 from diseases of the stomach. In such diseases, if in any, the bad effects of preservatives should be discoverable, for reasons that are no doubt obvious to the dullest intellect. Let us consider the statistics for 1900.

It is a well-known fact that city people consume more beer—salicylated and unsalicylated —than do country people, man for man. It is an equally well-known fact that country people raise nearly all the food consumed by themselves and that they are therefore not compelled to depend upon so-called "doctored" foodstuffs. The pork is that of their own salting. The butter is that of their own making. Their jams and jellies, fruit juices and homemade wines seldom know any stronger preservative than white sugar. their milk and cream are untampered with. What do the statistics of the United States Census collectors tell us about their superior health and particularly their freedom from affections of the stomach and alimentary canal, as compared with their "poisoned" brothers of the cities? The total for every State where registration of such facts was procured gave the death rate from such diseases as 18.1 in the cities and 20.7 in the rural districts. In Maine for every 16 city men that died from diseases of this kind there were 19 country men perished. In Massachusetts, for every 147 city men there were 166 country men; in Michigan for every 198 city men there were 207 country men; in New Hampshire for every 201 city men there were 213 country men; in New Jersey for every 196 city men there were 216 country men; in New York for every 182 city men there were 217 country men; in Rhode Island for every 134 city men there were 145 country men; in Vermont for every 194 city men there were 252 country men. Surely the people who denounce preservatives in foods can get but small consolation from such figures as these. Will they kindly come forward and tell us what it means? Can it be possible that nature herself has conspired to demonstrate what they believe to be the sacred truth is after all a mistake? Now let us examine these same figures geographically. Vermont, whose citizens are chiefly found in villages, small towns, and on farms shows a death rate, from diseases of the stomach, of 24.4, while Massachusetts, with its teeming multitudes of factory workers, compelled, from economy, to almost live on preserved goods, had next to the lowest death rate, from such diseases, of any State in the Union. For each 208 deaths from stomach diseases in rural Vermont there were only 151, or less than two-thirds the number in Massachusetts. The packed, ill-housed, salicylated beer-drinking, preserved-food-eating population, of factory covered Rhode Island, showed the lowest rate of any State. If salicylic acid damaged their stomachs very much they certainly do not show it in their vital statistics. Maine, with its practically successful attempt at prohibition, showed 184 deaths of its citizens from such diseases as against only 138 for the same number of persons in salicylated beer-drinking "Little Rhody."

If we turn now to the table showing "for each grand group in the United States, the proportion of deaths from diseases of the digestive system during the census year, per thousand deaths from known causes in the aggregate and by sex, for the cities and rural districts" we find the same preponderance for the whole United States as was shown by the first table for the registration States. We also see that it applies with equal force to a larger class than diseases of the stomach, but still to diseases that would primarily, be expected to first respond to any ill effects that might exist in preservatives. Each of the 21 grand geographical groups tells the same tale of death for country people as against city people. But now we come to a still more startling fact, that we hope our pure food advocates will study with great care. It is an undisputed fact that fewer women drink beer than men and that of those women who do drink beer proportionately less is used by them than by men. Their chances, therefore, for consuming large amounts of salicylic acid—as well as of alcohol, which is also antiseptic—are less than are the chances of the men. If salicylic acid is the dangerous thing, which anti-preservative men wish us to consider it, then those whose chances for using the largest amount of it are greatest should suffer most. This certainly must appeal to everybody as a fair inference. Now, what are the facts, as given by the statistics, for every one of the grand geographical groups? With very few exceptions, and these of regions containing great numbers of negroes, the deaths from diseases of the digestive system are highest among women. The refined, non-beer drinking women of the north, east, and west died faster of such diseases than did their beer drinking husbands. The coarse, masculine-like negro women of the south, with habits much like those of husband, brother and father, kept close to, or went below the death rate, from such causes, as males. Those of cities, who ape their more refined Caucasian sisters, showed a much closer agreement to the death rate of the whites. More of them died than of the men in the Southwest Central Region, the Southern Interior Plateau, and the Ohio River Belt. In the country part of these regions more men died than women. In the Gulf Coast Region more men died than women, of such diseases. The negro women of the Gulf Coast do not so readily imitate white woman's habits of life. If we now turn to the geographical totals we discover a few more significant indications that the disuse of preservatives does not conduce to lengevity as it ought to

if the opponents of their use are right. Take, for instance, the prairie regions of our country. There the deaths from diseases of the digestive system are 732 per ten thousand.

Compare this with the North Atlantic region. In the prairie region there is a majority of farmers and residents of small villages. In the North Atlantic coast region the majority are denizens of cities and extensive users of preserved foods and salicylated wines and beers. In this latter region there were only 476 deaths, from the diseases named, in ten thousand. In the still more rural population of the northwest timber belt, where cities are few and far between and where roads are bad and transportation expensive, the deaths were 746 in ten thousand. There beer is probably a rarity, preserved goods unnecessary and home produced provisions the rule. The prairie belt does not show as high a death rate as the northwest timber belt, even if it is the very highest for all other regions of the populous part of the United States. These are significant facts that we would like to have those explain who denounce the use of preservatives. What is it that makes the users of salicylated and borated foods appear to be so much freer from disturbances of the digestive system than those whose location would seem to negative the supposition that they use such foods freely? We will wait for a reasonable explanation of this condition of things from those who tell us that disaster and disease are the lot of the average user of foods preserved by antiseptics.

As if in mockery of the exceeding positiveness of the enemies of food preservatives the statistics supplied by our census gatherers show figures that are still more emphatically against the former at the very places where, of all others, they should have sustained their contention. Take, for instance, our ministers of the gospel, who are, as a class, opposed to the use of beer, and compare them with saloon-keepers, a very large proportion of whom drink beer, and what do we find? The death rate of clergymen is 23.5 per 1,000 and that of saloon-keepers only 13.3 per thousand. No matter what the causes may be that make so fearful a difference one might expect to find a better showing for the men who are not being dosed with "doctored" beer from morning till night, from January to December, as the saloon-keepers are. Neither is it disease of the nervous system nor greater age that wholly cause this wide difference. Since the death rate in clergymen from diseases of the digestive system was 106.5 and that of saloon-keepers, from the same cause, was only 60.4. The men whose stomachs and intestines were injured (?) by salicylic acid seem to have been benefited by the so-called injury, while those who, according to the theorizing enemies of protectives, should have had the fewest cases of this kind of disease had enormously the most. It is a favorite idea of these theorizers that the kidneys eliminate all salicylic acid and that these organs are injured by such eliminating. While the theory lacks a basis of fact we wish here to point out to them that the ministers had a death rate of 438.6 from diseases of the urinary system and the saloon-keepers only 126.6 from the same disease. Does this indicate that salicylic acid injures the kidneys? How glorious an illustration this would have been for them if the figures had been reversed.

Over three times as many ministers as saloon-keepers with such diseases constitutes a fact that we hope the anti-salicylic acid people will ponder over when next they discourse upon the dangers of this acid to the kidneys. Now, let us turn to the German element ot our population. They certainly get as much salicylated beer as any other of our citizens. Suppose we compare them with the Irish-Americans. The latter, as a rule, prefer whisky to beer, and as whisky is not salicylated it will give us a good chance to discover if there is damage done by the salicylic acid upon our German-Americans. In order the more certainly to settle the point regarding the part played by the alcohol in the matter let us consult the figures on alcoholism. Those Americans having Irish mothers have a death rate of 17.7 from alcoholism while those whose mothers are German have only a death rate of 6.1 from the same cause. With very nearly the same numbers of persons, within the registration regions, the Irish have nearly three deaths to every one among the Germans, from alcoholism. In diseases of the stomach the Irish-American death rate is 25.8 and the German-American only 17.7. Is it the salicylic acid which the Germans take that benefits them? Again, let us turn to the favorite idea of the foes of preservatives who claim that salicylic acid damages the kidneys. Here we have figures that bring us right down to the kidneys alone. The death rate among Irish-Americans from Bright's disease is given as 134.8 while for German-Americans it is only 86.8. Can it be possible that our census takers conspired with the antiseptic sellers and have falsified the returns? Turn to these returns in whatever direction we please and they all seem to indicate that there is something wrong with the theories of the enemies of food preservatives. While there are doubtless many factors at work causing the remarkable figures here presented, one thing seems quite certain, that they fail to indicate the slightest evidence of harm in the directions that harm should appear, if preservatives were injurious to public health.

In view of the fact that vital statistics give not the slightest encouragement to the idea that food preservatives tend to impair the action of our digestive organs, it might be well to enquire as to whether there is anything in the nature of the most efficient preservatives to, in the slightest degree, support the gratuitous assumption of their opposers. When we were ignorant of the distinction between enzymes and microbes we called them both ferments. How simple was the inference then made that what would hinder fermentation must hinder or hurt ferments. When

digestion was found to be a kind of fermentation, how easy it was to assume that anything that would kill a ferment, *i.e.*, microbe, would stop digestion. Prof. Sedgwick tells us in his Principles of Sanitary Science (p. 347) that "there is perhaps no subject in which popular errors are more prevalent than in sanitary science," and the fermentation error is one of the most common. It originated in ignorance and is perpetuated by the same agent. Enzymes are as distinct chemical bodies as are sugars or salts, and are therefore subject to chemical laws while microbes are living entities that are injured or killed by their special poisons. If salicylic acid is deadly to the yeast plant it in no way follows from this that it is destructive to pepsin, trypsin, diastase, or any other enzyme. If it arrests the fermentative action of the yeast by killing the plant what earthly connection can any sane mind see between this and inhibiting the production of peptone by keeping pepsin from supplying a hydroxyl group to albumin. Alcohol encourages the growth of the vinegar plant but interferes with the action of pepsin. Hydrochloric acid aids pepsin in its action but kills many kinds of pathogenic bacteria. Where then is there any room in sane thought for the conception that what will hurt a living ferment will hinder a nonliving enzyme. On the strength of this exceedingly silly delusion laws have been passed condemning and forbidding the use of food preservatives in a number of States. Analysts, ignorant of the origin of this superstition, keep repeating it as a truth, in their reports, from year to year. Nearly every substance under the sun has some retarding effect upon enzymes. This is not because they are able to kill living ferments. On the contrary many of them are the special food of such ferments. Salicylic acid is an exceedingly potent destroyer of organized or living ferments and there is no doubt but that like nearly every other substance it does interfere with the action of pepsin, trypsin and diastase. Its action on the latter, however, bears not the slightest relation to its action as a destroyer of bacteria. In the small amounts in which it is used in foodstuffs it retards digestion but little. When its compensating quality of acting as a stimulant to the stomach is brought into play it overcomes its retarding power and really becomes an aid to digestion. Under the head of Physiological Action, Bartholow says of it: "In small doses salicylic acid may stimulate digestion" (Materia Medica, 1903, p. 391). Cushny, in his Pharmacology and Therapeutics, tells us that "the salicylic preparations produce a slightly augmented flow of bile" (p. 416). They are therefore aids to the healthy action of the intestines.

If the oft-repeated charge that salicylic acid interferes with digestion was true—and as true as the enemies of food preservatives try to make it out to be—what of it? This question may stagger them. The claim that the rendering of part of the food we eat indigestible is injurious to health is another superstition of so-called sanitary science. In our present stage of civilization it would be a blessed thing for more than half the people if something could be given them to do just what these theorists imagine food preservatives do.

Brunton, in his interesting "Lectures on the Action of Medicines," says: "Constipation in ordinary people is generally due to the fact that the food they take has little or none of the stimulating qualities that ordinary diet would have in uncivilized countries. . . . They ground their wheat in the handmill, and then baked their bread of this coarse meal, but such meal is hard and gritty, and contains a great deal of indigestible residue, which would tend to keep the bowels of those taking it regularly active. Nowadays we have wheat so finely ground that all the indigestible outer part is taken away from it, and we have nothing but the starchy interior of the wheat remaining." It is a trite saying that most men eat too much and it would be a blessing to them if someone would supply them with something that would render part of what they eat indigestible and at the same time antiseptic. Every step in our progress toward the preventing of disease germs being carried into us by our nitrogenous food has resulted in lessening the digestibility of that food. Cooking renders meat, eggs, milk, fish, etc., harder to digest. The use of salt, smoke, drying, alcohol, and vinegar all increase the indigestibility of the food on which they are used. Sterilizing does the same. Where then is the sense of hurling condemnation at the newer chemical food preservatives for doing just what all other methods of protecting food from infection do, particularly as the so-called evil complained of is really not an evil but a blessing. The ideal, perfectly aseptic condition of food is something everybody would like to have. But it should remain aseptic till eaten. The time will probably never come when such an ideal will be reached.

The attempt of half informed people to hasten its arrival, by bowing down to the fetish of legislation, can only accomplish what all crude attempts at reform invariably accomplish, retardation of progress. Imagine laws being passed forbidding the use of antiseptics by medical men because their action produces results inferior to the aseptic treatment of wounds. What would result? It is plain to be seen by every medical man that aseptic conditions are only possible under certain favorable conditions. Much as one might wish to treat every wound aseptically in practice it is impossible. A law compelling aseptic treatment or none would simply be a law signing the death warrants of thousands of innocent victims. The conditions here are perfectly analogous to those that exist in the protection of food. Can it be possible that our State laws which prohibit the use of modern antiseptics in food are the signed death warrants of multitudes of people? To many intelligent men and women it looks that way and the vital statistics of our country point in the same direction.

MEDICAL PROGRESS.

OBSTETRICS AND GYNECOLOGY.

Tuberculosis and Pregnancy.—An excellent summary of the views held at the present day of this important question is given by W. Hahn (Berl. klin. Woch., Dec. 28, 1903). He also reports five cases which came under his own observation. He states that pregnancy is a severe complication of tuberculosis, the severity of which increases with each pregnancy. Important among the prophylactic measures should be the prevention of conception among tuberculous women. If pregnancy has taken place the woman should be kept under careful medical observation, and if the tuberculous disease grows worse, abortion should be strongly recommended. During the later months of pregnancy the induction of premature labor does not offer any advantages over labor at full term, and is fraught with seriousness for a tuberculous patient. Moreover, as a tuberculous mother may give birth to a healthy child with fair chances of good health later on, it would be unfair to needlessly sacrifice the life of the infant. He does not believe in universally interrupting the pregnancy as advocated by Maragliano and Hamburger.

Separation of a Normally-situated Placenta.—The early separation of the placenta during labor is a rare and dangerous complication, and it is not commonly known that this accident may happen with a normal placental insertion. G. Schickele (Münch. med. Woch., Dec. 22, 1903) states that hemorrhage early in labor is the prominent symptom; it may be internal or external, sudden or gradual in onset and ofttimes its effects upon the system are rapid and pronounced. In the worst cases the entire placenta separates at once, but more often the dissection takes place more slowly and by virtue of a retroplacental hematoma. The placenta sometimes falls out of the vulva directly after birth, sometimes the third stage takes a perfectly normal course. The prognosis is fair and the treatment calls for dilatation of the cervix and rapid delivery with the forceps or version. Since the fetus is generally dead, craniotomy will often be indicated. The etiology is obscure, but often a necrosis of the decidua is found, probably due to vascular disease.

Hernia of the Genital Organs into the Inguinal Canal.—Hernia containing either Fallopian tubes or ovaries is a very rare condition, says Leopold Le Noüene (Gaz. de Gyn., Nov. 15, 1903). There are in the literature not more than a dozen cases of hernia in the inguinal region containing the uterus outside of pregnancy. The writer has observed two cases in the service of Dr. Sorel; one, a simple hernia of the adnexa and the other a hernia of the uterus and the adnexa, the tubes of which were in a suppurating condition. In the first case the right ovary seemed to have entered the sac and to have been followed by the tube, which, according to Lockwood, always takes place in this condition. Curveilhier and Dolbeau hold that the tube is the first to prolapse and the ovary then follows it. The majority of genital inguinal hernia show either inflammatory or neoplastic changes in the genital organs (cystic degeneration, dermoid or hydatid cyst or cancer). Peuch reports 98 cases of malformations where there were various anomalies, such as female hermaphrodism, absence of the uterus or an infantile state of this organ. It is certain that in the larger majority of the cases the inguinal hernia is accompanied by some malformation of the genital organs. In the author's second case, both tubes had entered the hernial sac first, but the ovaries had been dragged in later. There was also present a double pyosalpingitis. Operation was rendered difficult because of this condition. The patient was operated upon because it was thought that she had a strangulated hernia, but there were no signs or symptoms of intestinal obstruction present.
